ABSTRACT

SUNFLOWER YIELD ESTIMATION USING SYNTHETIC APERTURE RADAR AND OPTICAL DATA

İrem Ecem ASLAN

Master of Science, Department of Geomatics Engineering

Supervisor: Assoc. Prof. Dr. Saygın ABDİKAN

2023

The scope of the presented thesis, it is aimed to obtain highly accurate yield estimation by applying Artificial Neural Networks (ANN) and Simple Linear Regression (SLR) methods on sunflower parcels in a certain area using Sentinel-1 Synthetic Aperture Radar (SAR) and Sentinel-2 optical satellite images. The 2018 Sentinel-1 and Sentinel-2 satellite images of the sunflower farming region in the Zile district of Tokat province were examined. First, the Normalized Difference Vegetation Index (NDVI), Normalized Difference Vegetation Red-Edge-1 (NDVIR1), Optimized Soil-Adjusted Vegetation Index (OSAVI), and Inverted Red-edge Chlorophyll Index (IRECI) were obtained from Sentinel-2 satellite images. Then, the correlations between these indices and reference yield data were examined separately. The highest correlation in all examined vegetation indices examined was determined on 30 June, 8 July, and 10 July. Using the SLR method, OSAVI ($R^2=0.75$ RMSE=22.47 kg) gave the best result during the heading period on 30 June. However, when the indices are processed as a single input value in the ANN method, the best result is obtained from NDVI ($R^2=0.76$ RMSE=22.07 kg) in the 30 June heading period. The ANN method gave

better results than the linear regression method on all dates. The best estimation study was made with the ANN method in the NDVI and NDVIR1. When the four indices were processed together as input values, the best result was again obtained during the heading period on 30 June ($R^2=0.78$ RMSE=21.59 kg). In the ANN method, it was concluded that using the indices together as inputs reduces the error rate in yield estimation. The phenological stages and yield values of the sunflower plant were determined with high accuracy by the ANN method. Secondly, backscattering and coherence values obtained from Sentinel-1 satellite images produced close values in both VH and VV polarizations in most of the dates considered, but in the ANN method, VV polarization produced better values than VH polarization. When the yield estimation was made with the backscatter values, the best result in the ANN method was obtained in the VV polarization on June 29 ($R^2=0,09$ RMSE=42,46 kg). When the yield is estimated with the coherence values, the best result was obtained on the 5th of July-11th in the VV polarization ($R^2=0.01$ RMSE=46.24 kg). The results showed higher errors compared to optical data. When the R^2 value and the average RMSE are compared with the values obtained from the indices values, it is seen that the contribution of the backscatter and coherence values is very little or not in the yield estimation. The use of backscatter and coherence values alone in the yield estimation is not recommended for this study. Lastly, when the values obtained from optical and SAR satellites are used together, the best result was obtained during the heading period between 29 June - 5 July ($R^2=0.67$ RMSE=26.83 kg). The estimated yield values were found with acceptable accuracy. However, the values did not improve.

Keywords : Sunflower, Sentinel-1, Sentinel-2, ANN, Yield estimation

ÖZET

SENTETİK AÇIKLIKLI RADAR VE OPTİK VERİLER KULLANILARAK AYÇİÇEĞİ VERİM TAHMİNİ

2023

Sunulan tez kapsamında, Sentinel-1 Sentetik Açıklı Radar (SAR) ve Sentinel-2 optik uydu görüntülerini kullanarak belirli bir alandaki ayçiçeği parsellerinde Yapay Sinir Ağları yöntemi (YSA) ve Lineer Regresyon yöntemi uygulanarak verim tahmininin yüksek doğrulukla elde edilmesi hedeflenmiştir. Tokat ilinin Zile ilçesinde yer alan ayçiçeği tarım bölgesinin 2018 yılına ait Sentinel-1 ve Sentinel-2 uydu görüntüleri incelenmiştir. İlk önce, Sentinel-2 uydu görüntülerinden Normalleştirilmiş Fark Bitki Örtüsü İndeksi (NDVI), Normalleştirilmiş Fark Bitki Örtüsü Kırmızı Kenar 1 İndeksi (NDVIR1), Optimize Edilmiş Toprak Ayarlı Bitki Örtüsü İndeksi (OSAVI) ve Ters Kırmızı Kenarlı Klorofil İndeksi (IRECI) elde edilmiştir. Daha sonra bu indeksler ile referans verim değerleri arasındaki korelasyonlara ayrı ayrı bakılmıştır. İncelenen tüm bitki indekslerinde en yüksek korelasyon 30 Haziran, 8 Temmuz ve 10 Temmuz tarihlerinde elde edilen verilerle belirlenmiştir. Lineer regresyon metodunda en iyi sonucu, OSAVI ($R^2=0,75$ RMSE=22,47 kg) 30 Haziran tarihinde çiçek tablası oluşum döneminde vermiştir. Ancak, YSA yönteminde indeksler tek girdi değeri olarak işleme alındığında, en iyi sonuç 30 Haziran tarihinde çiçek tablası oluşum döneminde NDVI'dan ($R^2=0,76$ RMSE= 22,07 kg) alınmıştır. YSA yöntemi, lineer regresyon metodundan tüm tarihlerde daha iyi sonuç vermiştir. En iyi tahmin çalışması NDVI

ve NDVIR1 verileriyle sinir ağı yöntemiyle yapılmıştır. Dört indeks birlikte girdi değeri olarak işleme girdiğinde, en iyi sonuç 30 Haziran ($R^2=0,78$ RMSE= 21,59 kg) tarihinde yine çiçek tablası oluşum döneminde alınmıştır. YSA yönteminde, indekslerin girdi olarak birlikte kullanılması, verim tahmininde hata oranını azalttığı sonucuna varılmıştır. YSA yöntemi ile ayçiçeği bitkisinin fenolojik aşamaları ve verim değerleri yüksek doğrulukla belirlenmiştir. Daha sonra, Sentinel-1 uydu görüntülerinden geri saçılım ve uyumluluk değerleri hem VH hemde VV polarizasyonunda üretilmiştir. Ele alınan çoğu tarihte, incelenen polarizasyonlar birbirlerine yakın değerler üretmiştir ancak YSA yönteminde, VV polarizasyonu VH polarizasyonuna göre daha iyi değerler üretmiştir. Geri saçılım değerleri ile verim tahmini yapıldığında, YSA metodunda en iyi sonuç 29 Haziran VV polarizasyonunda alınmıştır ($R^2=0,09$ RMSE= 42,46 kg). Uyumluluk değerleri ile verim tahmini yapıldığında en iyi sonuç 5 Temmuz-11 Temmuz tarihinde VV polarizasyonunda alınmıştır ($R^2= 0,01$ RMSE= 46,24 kg). Bulunan sonuçlar kabul edilebilir doğrulukta bulunmamıştır. R^2 değeri ve ortalama RMSE, indeks değerlerinde elde edilen değerlerle kıyaslandığında geri saçılım ve uyumluluk değerlerinin verim tahmininde katkısının çok az yada olmadığı görülmüştür. Geri saçılım ve uyumluluk değerlerinin tek başına verim tahmininde kullanılması bu çalışma için önerilmemektedir. YSA yöntemiyle, optik ve SAR uydularından elde ettiğimiz değerler birlikte kullanıldığında, en iyi sonuç 29 Haziran- 5 Temmuz tarihinde çiçek tablası oluşum döneminde alınmıştır ($R^2=0,67$ RMSE= 26,83 kg). Tahmin edilen verim değerleri, kabul edilebilir doğrulukta bulunmuştur. Ancak değerler iyileşmemiştir.

Anahtar Kelimeler: Ayçiçeği, Sentinel-1, Sentinel-2, YSA, Verim tahmini

ACKNOWLEDGEMENTS

First, I would like to express my gratitude to my supervisor Assoc. Prof. Dr. Saygın Abdikan, for his dedicated attention and his efforts.

I would like to thank Research Assistant Ömer Gökberk Narin for providing me with the images of Sentinel-2 and supporting me with his comments about my work.

I would like to thank my dear family who supported me during this process.

1. INTRODUCTION

1.1 Purpose and Scope

It has become very difficult to ensure food safety, due to the increasing population and negative meteorological effects. Therefore, it is very important to provide the timely processing of agricultural products and reliable information about crop development. The evolving era and technology aim to learn as quickly as possible, reliably, and easily. For this, remote sensing technologies, which provide us with the necessary facilities and are used in smart agriculture applications, seem to be a very good option. Remote sensing technology by satellite is providing more and more accurate and reliable results by using various methods for these requirements. One of the most widely used areas of remote sensing techniques is agricultural applications. Such as the phenological time of the plant, yield estimation, creating a product mold, increasing product yield, and determining soil salinity [1]. For example, vegetable oils are especially important in people's nutrition. Sunflower (*Helianthus annuus* L.), is one of the world's leading sources of vegetable oil production. It is an oilseed plant with a wide planting area and production in the world. The sunflower plant can grow in moist and dry conditions and provides easy adaptation to the soil. This is the advantage of the sunflower plant [2]. The ongoing climate changes around the world are causing extreme temperatures, drought, and salinity, which are certain stress components in agriculture. These effects decrease the yield and cause crop loss [3]. Particularly, salinity is one of the factors leading to a decrease in sunflower production by more than 60% worldwide [4]. The salinity tolerance of sunflower is 8.4 dS / m^{-1} , and an increase in each salinity unit relative to the tolerance level reduces the yield amount of sunflower seeds by about 5% [5]. Therefore, it is very important to get the maximum yield from the sunflower plant. The use of remote sensing techniques has become quite widespread in order to make faster and more reliable yield estimates.

Crop yield estimation is seen as an important requirement for taking precautions against drought in advance, ensuring food security for many years, monitoring plant agriculture in fast and large areas, and increasing the well-being of farmer families. In crop yield estimation studies, yield estimation is most often performed

based on land reports, but this method is a time-consuming, costly method with a high tendency to error [6]. Crop yield estimation and growth phases can be performed with both optical and Synthetic Aperture RADAR (SAR) satellites. Optical and SAR data can be used together to complement each other, depending on the study's conditions. Optical sensors operating in the optical wavelength portion of the electromagnetic spectrum are placed in satellite systems that allow viewing all or part of the earth. Different spectra represent different landforms. They can be distinguished by processing satellite images. These high resolution images are highly preferred in agricultural applications due to their low cost, ease of processing, and short-term reproducibility. Vegetation indices are obtained by different combinations formed between different bands in optical satellite images and the proportioning of these combinations to each other. Vegetation indices play a crucial role in monitoring changes in vegetation [7]. In yield estimation studies, vegetation indices are preferred because they give highly accurate results. The most widely used of these is the Normalized Difference Vegetation Index (NDVI), presented in 1974 [8]. Different vegetation index types can be used in crop yield estimation studies and other agricultural application studies. The vegetation index types to be used should be determined by the purpose of the study [9,10]. The Optimized Soil-Adjusted Vegetation Index (OSAVI) is one of the indices that, like the NDVI, is used as a predictive indicator of crop growth. Product phenology plays an important role as a series of growth stages and in determining the grain yield of a single product property [11]. The study conducted by Marino and Alvino (2019) also confirmed the ability of OSAVI to take into account the brightness of the soil [11]. The Inverted Red-Edge Chlorophyll Index (IRECI) highlights the amount of chlorophyll. Frampton et al. (2013) evaluated the biophysical variables with Sentinel-2 images. They stated that the IRECI was better than the NDVI in measuring the chlorophyll content of the canopy and showed high performance in the study [12]. Optical satellite images have also some disadvantages. As the optical satellites have passive sensors, they use the sun as an energy source and are affected by weather conditions, and can not be used at night. SAR satellite images are formed by determining the ratio between the electromagnetic energy sent to the earth's surface and the electromagnetic energy returned to a receiver [13]. The satellite sends the energy generated by itself to the Earth, and the energy scattered back is detected and recorded numerically through an antenna. The

energy returned to the sensor is called backscatter [14]. Backscatter is an important quantity that shows the reflectance values of the parcels opened on the radar image relative to each other. It is used as an important value in determining the different phenological stages of the crop in agricultural monitoring applications [15]. For example, Nasirzadehdizaji et al. (2021), confirmed that there is a high correlation between the backscatter value obtained from the Sentinel-1 radar satellite image and the growth stage of the crops [15]. The coherence value produced from several SAR images at different times can be used as a quantification to determine the signal-to-noise ratio [16]. For example, Amherdt et al. (2022) investigated the contribution of the coherence value to the backscatter value obtained from the Sentinel-1 satellite image for soybean and maize analysis. Consequently, C-band and VV polarized data may be a suitable parameter to map soybean and maize, while adding coherence to the backscatter information. However, they concluded that when the preferred variables for classification are a combination of dual-polarized (VV and VH) backscattering, it is not relevant to add coherence because of less enhancement and high computing overhead [17]. Unlike optical satellites, SAR satellites use their energy sources. They may perform day or night and are unaffected by the weather, but radar systems, display errors due to topographic effects, and speckle-noise effects on images are disadvantageous compared to optical systems and their processing and evaluation are a bit more complex [18].

Due to the various limitations of optical and SAR satellites in yield estimation studies, there is a growing interest in the joint use of both for agricultural purposes. For this purpose, there are many studies in which optical and radar satellites are used together in agricultural applications [18]. Fiezal et al. (2016) estimated the yield of crop maize plants using the artificial neural network method using optical (Spot-4/5, Formosat-2) and microwave (TerraSAR-X, Radarsat-2) satellite images. They determined that for the maize plant, the optical satellite gave the best estimation result in the red wavelength, and the adaptation of the backscatter values remained lower in the yield estimation [19]. In their study, Ranjan and Parida (2021) tried to estimate the yield estimation of rice crops using three different methods using MODIS satellite from optical satellites and Sentinel-1 satellite images from radar satellites together. As a result of this, they stated that when they

used the Multiple Linear Regression (MLR) models according to the optical image, they got better results than the radar image based on the SAR satellite [22]. The preferred method as well as the satellite image used in crop yield estimation studies can positively affect yield estimation. Artificial Neural Networks (ANN) and linear regression are broadly preferred in agricultural applications, especially for yield prediction. Simple Linear regression (SLR) is a conventional method, it establishes a linear relationship between satellite images and vegetation indices, phenological stages of plants can be examined and yield estimation can be studied. ANN is a relatively new method compared to the SLR method [23]. ANN symbolically represents interconnected processing neurons or nodes in the human brain, and is used to develop the relationships between variables and the models created [24]. ANN is a trial and error method that has many features of the human brain, it is a method that learns with experience, they make new inferences by reducing the previously learned information to general. In many studies, it has been stated that the inferences made with this method give high accuracy. Ballesteros et al. (2020) used multispectral images obtained with an Unmanned Aerial Vehicle (UAV) and compared the ANN and other linear modeling techniques to estimate the yield of the Vineyard. As a result, they stated that the ANN technique gave much better results than other SLR models [25]. Ashapure et al. (2020) presented a machine-learning approach for cotton yield estimation which has been developed using multi-temporal remote sensing image acquired by a UAV system. Three categories of product attributes generated from UAS data were used in the proposed model's ANN to predict efficiency. The performance of the ANN model was compared with Support Vector Regression (SVR) and Random Forest Regression (RFR). The comparison results revealed that the ANN model performs better than SVR and RFR. It was stated that the ANN model technique of their cotton yield estimation is a safe model that can be used in crop yield estimation [26].

1.2. Aim of the thesis

The study aims to obtain accurate yield estimation and phenological time by applying the ANN method on sunflower parcels in a certain area using Sentinel-1C-band data and multi-spectral Sentinel-2 satellite images. In addition, it is aimed to examine the relationship between vegetation indices calculated by creating time

series and yield. The main objectives of the research can be listed in detail as follows;

- Performing high-accuracy yield analysis using optical and radar satellites together with NDVI and NDVI_{re1}, which are highly accurate spectral index options in the field of agriculture, and IRECI and OSAVI, which are index types that have not been studied much before.
- Investigation of the contribution of Sentinel-1 and Sentinel-2 satellites in achieving high accuracy results in yield analysis with the ANN method.
- Investigation of the effects of using vertical-vertical (VV) and vertical-horizontal (VH) images of SAR satellite.
- Contribution of coherence feature derived from multi-temporal VV and VH data.
- Determination of the most appropriate phenological time in yield estimation.
- In addition, it is aimed to investigate to what extent this study can contribute to local institutions and organizations.

In this study, using backscatter, and coherence of Sentinel-1 and 4 vegetation indices of Sentinel-2 satellite data will be produced separately for each image. By using the ANN method, yield estimation will be made on the test parcels where the sunflower plant gives the highest correlation in the phenological growing stage. The SLR and ANN methods were compared.

1.3 Thesis Structure

There are seven chapters in the thesis. The first part presents the role of remote sensing in agriculture and summarizes the purpose of the study. The second part includes the studies done with optical and SAR satellite images in the past and reveals the difference in this study. The third part covers the study area and materials and examines the optical and SAR satellites and the data we obtained from these satellite images. In the fourth part, the preprocessing steps of satellite images are explained. The fifth part examines the result of the study separately and together for optical and SAR satellites. The sixth chapter includes discussion, and the seventh and final chapter contains general conclusions and future work.

2. RELATED WORK

In the literature, there are many studies on agricultural product detection by remote sensing methods. These studies are promising for agricultural product detection. Therefore, in recent years, like all other agricultural products, studies on the sunflower plant have increased.

In the field of crop agriculture, many different studies such as yield estimation, creation of time series, determination of phenological phases of the product, length determination, estimation of leaf area index, and determination of soil salinity have been carried out and different methods have been developed. Sometimes only optical images, sometimes SAR satellite images, and sometimes both satellite images were used in the studies and the results were examined. These studies carried out cover different remote sensing techniques and different methods from the past to the present.

Fieuzal and Baup (2016) estimated leaf area index (LAI) and crop height (CH) of sunflower plant using optical and SAR satellite images from selected sunflower fields from Southwest France. They used TerraSAR-X, Radarsat-2, Alos, Formosat-2 and Spot-4/5 satellites and benefited from NDVI and Modified Triangular Vegetation Index (MTVI2). As a result, they obtained the highest results for L_{HH} , C_{HH} polarization and NDVI for LAI and CH. But, they stated that more analysis is required to obtain more accurate and precise results [27].

Wenzhi et al. (2017) also investigated the effectiveness of statistical models created by Partial Least Squares Regression (PLSR) and ANN in predicting the yield of sunflower plants. Data from two years of sunflower field trials on plant growth under various salt levels and nitrogen (N) application rates were utilized to calibrate and validate statistical models in Hetao Irrigation District, Inner Mongolia, China. Precise indices as inputs for the estimation of seed yield with the PLSR model, all measured indices used in comparison with a comparable accuracy (Root Mean Square Error (RMSE) = 0.81 t ha⁻¹ and Coefficient of Determination (R^2) = 0.77) (RMSE) = 0.93 t ha⁻¹, R^2 = 0.69). They concluded that ANN outperforms PLSR for estimated yield in different combinations, therefore it is a method that can be used to determine yield [28].

Ameline et al. (2018) estimated the yield of maize plants using an agro-meteorological model, using data from the Southwest of France, using Landsat-8 optical satellite imagery and Sentinel-1 SAR satellite image. As a result, they stated that the estimation was lower with the use of these two satellites together, but it was an acceptable result [20].

Narin (2019), determined NDVI and NDVI_{red} from Sentinel-2 images gave high accuracy when RMSE values are taken into account in the phenological stages of sunflower crop yield estimation by linear regression method [6].

Narin et al. (2021), examined the relationship between NDVI_{red} and NDVI obtained from the Sentinel-2 satellite. They examined Linear Regression, Convolutional Neural Networks (CNN), and ANN techniques using vegetation indices and estimated the yield of sunflower plants. As a result of this study, they obtained the best results with the CNN approach using NDVI with RMSE 20,874 Kg/da on 30 June 2018 and stated that there was no critical difference between the indices, and they obtained the finest outputs with the CNN method [29].

Alebele et al. (2021) estimated rice grain yield by Gaussian kernel regression method with Sentinel-1 interferometric coherence data using the red edge difference vegetation index (RDVI1) and various indices obtained from Sentinel-2 optical satellite images. As a result, they concluded that the coherence values can be used in the analysis of phenology levels of the crop and the Gaussian kernel method can be used as a preferred method in yield estimation studies [21].

Narin and Abdikan (2022) determined the phenological growing stages of the sunflower plant and estimated the yield by utilizing the seasonal Sentinel-2 images and producing ten different indices from these images. They reported that the best estimate was made by NDVI on 30 June (RMSE=10.80 kg/da and $R^2=0.74$). They came to the conclusion that Sentinel-2 satellite data might be utilized to monitor the growth of the sunflower plant and to gather yield information roughly three months prior to harvest. [30].

Amankulova et al. (2022) used Sentinel-2 images to determine sunflower yield with RFR, in the study they conducted in Mezohegyes, Hungary. They used Sentinel-2 images obtained between April and September. They stated that the best time to estimate sunflower yield from Sentinel-2 images was between 85 and 105 days at

the flowering stage, with high accuracy with RMSE values ranging from 121.9 to 284.5 kg/ha for different test areas. They concluded that they could predict sunflower yield 3-4 months before harvest [31].

Cui et al. (2022) studied to estimate soil salinity under sunflower cover by taking aerial images of four growing stages of sunflowers from six study areas between July and September 2021 in Hetao Irrigation Zone in Inner Mongolia Province, China, with a UAV. They investigated the correlation between vegetation indices (VIs), salinity indices (SIs), electrical conductivity (EC), leaf area index (LAI), plant height (H), three crop parameters and Soil Salt Content (SSC). Optimal parameters were determined and the SSC prediction model was created using ANN, Random Forest, and MLR algorithms, respectively. As a result, they determined that ANN and Random Forest method outperform MLR in SSC prediction application and ANN is the best prediction model for the four growth stages of sunflowers [32].

Khalifani et al. (2022), determined sunflower seed yield in both normal and salinity stressed conditions, using MLR, ANN, and CNN approaches. They then determined the most effective parameters defined in both conditions. As a result, they concluded that head diameter parameter was the characteristic of sunflower seeds that had the most influence, and that, when compared to MLR and ANN, the CNN approach provided the most accurate prediction for sunflower seed [33].

Bognár et al. (2022) determined the yield estimation of corn, winter wheat, sunflower, and rapeseed in Hungary with 16 different vegetation indices using the MODIS optical satellite. As a result, they concluded that the yield accuracy can be increased by adding meteorological data [34].

A.Sadenova et al. (2022) conducted a study in East Kazakhstan applying the Gaussian function and Levenberg-Marquardt approach, they determined the yield of sunflower with NDVI over a 7 day period. They determined that the estimation error, depending on the week, varied between 0.67% and 10.7% each year, for the examined period. This was considered a respectable accuracy in seasonal analysis [35].

Abdikan et al. (2023), used Sentinel-1 and Sentinel-2 satellite images, to estimate the crop height of sunflowers. They used SLR, MLR, ANN, EXtreme Gradient

Boosting (XGBoost), and CNN methods. As a result, the best models in all four methods were constructed using rvh, concluding that NDVIred contributed more from their previous work than NDVI. They determined that the ANN gave the minimum error (RMSE = 3.083 cm) for the stem elongation span, while the second best result was given at the flowering stage of the CNN (RMSE = 8.731 cm) [36].

3. STUDY AREA AND MATERIALS

This study was carried out on 48 sunflower parcels in the south of the Zile district of Tokat province. Study area parcels were taken from the study of Narin (2019) [6]. Sentinel-1 with Sentinel-2 satellite images, which contain 48 sunflower parcels, were downloaded taking into account certain periods. The coherence and backscatter values were obtained from the Sentinel-1 image and the four index values (NDVI, NDVR1, IRECI, and OSAVI) were obtained from the Sentinel-2 satellite image. In this section, the study area, the phenological stages of the sunflower plant, and the satellites used are explained in detail.

3.1 The Study Area

The test site was chosen from the cropland of Tokat province located between the Fatih and Kurşunlu villages of the Zile district. Zile is one of the oldest settlements in Anatolia, it is Turkey's 169th-largest district in terms of area [37]. Zile Province is between 39° 52' and 40° 55' north latitudes and 35° 27' and 37° 39' east longitudes.

Zile district is located 67 kilometers west of Tokat province in the central Black Sea. The weather in the region is hot and dry during the summer season and snowy and cold in winter. From June to September the weather is hot. From December to February the weather is cold. It is usually rainy in April, May, June, November, and December.

Figure 3.1. Tokat Province Zile District

The average air temperatures of the Zile district by month are shown in Figure 3.2 [38].

Figure 3.2. Average Air Temperatures of Zile District

The average cloudy, sunny, and rainy days of Zile District are shown in Figure 2.3 [39].

Figure 3.3. Cloudy, sunny, and rainy days in the Zile District

The cadastral borders of 48 sunflower parcels, which are considered the study area, between Fatih and Kurşunlu villages, on the Google Earth image (blue polygons) are shown in Figure 2.4.

Figure 3.4. Google Earth view of 48 parcels of the sunflower field

3.2 Phenological Stages of the Sunflower Plant

Sunflower, which has a wide cultivation area and production in the world, is also used as an important raw material in the oil industry, cosmetics, and chemical industries. It is a nutritious animal feed due to its high content of protein, carbohydrates, fat, and phosphorus [40]. In 2021, 49.27 million tons of sunflower was produced. And most of it was used for oil production [41]. The sunflower plant is an annual and summer plant. It is grown in temperate climatic regions where the average temperature in July does not fall below 18-19 °C. It is a relatively drought-resistant plant due to its strong and deep root system. Sunflower does not like very humid areas, in case of high relative humidity, it is affected by the negative effects of diseases that cause rot [42]. Sunflowers can adapt to different soil types. For example, it can grow in sandy or clay soils. Deep, and rich in organic matter, alluvial soils are very suitable for sunflower cultivation, but it is difficult to grow in soils with high salinity. For the germination of sunflowers, the minimum soil temperature should be 8-10 °C. Sunflower is resistant to cold, but it is highly affected by frost which occurs when the temperature drops below -4 °C [43].

The appearance of the sunflower plant at each stage is shown in Figure 3.5.

Figure 3.5. The view of the sunflower plant at each stage [6].

The stages shown in Figure 3.5 were evaluated in the code scale of Biologische Bundesanstalt, Bundessortenamt and CHEmical industry(BBCH). The BBCH code

is classified under 8 main headings. These are the stages of soil preparation-planting, leaf development, root elongation, flower tray formation, flowering, fruit ripening, ripening, and harvesting, respectively [44]. The planting of the sunflower plant is usually done in early April-mid-May. Early sowing significantly increases yield. Harvest operations are applied at the end of August and the beginning of September. Approximately four months later from the planting process, the sunflower plant begins to be harvested [6]. Yield information for each parcel is given in the appendices.

3.3 Optical Remote Sensing Data

In the study, 23 level-2A optical images of Sentinel-2 satellites from 2018 were used. The selected display dates cover the leaf development stage of the sunflower plant through to the harvest stage. Selected optical image dates are shown in Table 3.1.

Tablo 3.1: Available optical image dates

Satellite name	Image Date	Satellite Name	Image Date
Sentinel-2A	26 April 2018	Sentinel-2B	13 June 2018
Sentinel-2A	29 April 2018	Sentinel-2B	30 June 2018
Sentinel-2B	4 May 2018	Sentinel-2A	8 July 2018
Sentinel-2B	14 May 2018	Sentinel-2B	10 July 2018
Sentinel-2B	16 May 2018	Sentinel-2A	18 July 2018
Sentinel-2B	24 May 2018	Sentinel-2A	25 July 2018
Sentinel-2A	26 May 2018	Sentinel-2A	14 August 2018
Sentinel-2B	3 June 2018	Sentinel-2A	17 August 2018
Sentinel-2A	5 June 2018	Sentinel-2A	24 August 2018
Sentinel-2A	8 June 2018	Sentinel-2A	27 August 2018
Sentinel-2B	10 June 2018	Sentinel-2B	1 September 2018
		Sentinel-2A	13September 2018

The Sentinel-2 satellite is a Multi-Spectral image acquisition satellite used to provide optical images supported by European Space Agency (ESA). Multi-spectral images obtained by satellite sensors can display visible and infrared wavelengths separately. The satellite has 13 spectral bands which have various spatial resolutions [45]. Each image representing a wavelength range is called a band. Sentinel-2 is frequently preferred in monitoring applications because of its high imaging frequency, spatial resolution options, and coverage area [13]. As the spatial resolution increases, it becomes easier to detect the reflection values of objects. The distinguishability of objects from each other is increased, therefore, interpretation becomes easier. The size of the objects affects the reflection values of the pixels that make up the image [46]. The reflection properties of objects participate in the reflection value of pixels and these values are used in determining the phenological stage of the plant and in yield estimation studies.

In this study, Sentinel-2A and Sentinel-2B satellites that started their operations in 2015 and 2017, respectively were used together. These missions are placed in the same orbit at 180 degrees from each other. This ensures that a 10-day return visit cycle is completed in 5 days [47]. The band characteristics of both satellites are shown in Table 3.2.

Table 3.2: Spectral properties of Sentinel-2A/B satellites.

Band Name	SENTINEL-2					
	Sentinel-2A			Sentinel-2B		
	Resolution (m)	Wavelength (nm)	Band Width (nm)	Resolution (m)	Wavelength (nm)	Band Width (nm)
1	60	442.7	27	60	442.2	45
2	10	496.6	98	10	492.1	98
3	10	560.0	45	10	559	46
4	10	664.5	38	10	665	39
5	20	703.9	19	20	703.8	20

10	60	1373.5	75	60	1376.9	76
11	20	1613.7	143	20	1610.4	141
12	20	2202.4	242	20	2185.7	238

Sentinel-2 satellites provide images at different levels. Level-1C has Top-Of-Atmosphere reflectance. The pre-processing steps should be applied to images at the level of Level-1C and the image should be improved [48]. Therefore, Level-2A data with Bottom-Of-Atmosphere reflectance have been also distributed. In this study, Level-2A level images were used and no additional pre-processing steps were applied.

In this study, four different indices were used. The indices and bands used are shown in Table 3.3.

Table 3.3: Indices and Equations

Index Name	Equations	Reference
NDVI	$(B8-B4)/(B8+B4)$	Rouse et al. 1973
NDVIR1	$(B8-B5)/(B8+B5)$	Gitelson et al. 1994
OSAVI	$(B8-B4)/(B8+B4+0.16)$	Rondeaux et al. 1996
IRECI	$(B7-B4)/(B5/B6)$	Rondeaux et al. 2013

Vegetation indices are used to increase the distinguishability of land cover in agricultural applications. They are frequently used because high accuracy results are obtained in yield estimation studies and other agricultural applications [29, 35]. With the increase in spectral resolution of optical sensors, new indices have started to be produced by proportioning the bands to each other and they have been tried

according to the purpose of the study. Among these indices, OSAVI and IRECI indices are some of these indices. While the IRECI index highlights the amount of chlorophyll, the OSAVI index is more prominent in grain yield estimation studies [11].

3.4 SAR Remote Sensing Data

The backscatter value is measured to distinguish objects from each other. Low backscatter on a surface or object causes a low pixel value to result in a dark near-black color, while high backscatter results in a high pixel value, causing the pixel color to appear close to white [49]. The amount of backscatter is a variable that can change. This change also depends on some parameters. These are radar system parameters (frequency, polarization, incidence angle of reflected signals) and target system parameters (surface roughness ratio, geometric shape, moisture).

3.4.1 Frequency

Frequency is used to understand the depth to go under the surface of an object and to measure the surface roughness in absolute (relative) terms [50]. The wavelengths used in microwave active systems alter according to the response of the targets in the specified ranges. The X band between the 2.4 cm and 3.75 cm wavelength range is backscattered from the surface of the targets and is mostly used for military purposes. The C band, with wavelengths between 3.75 and 7.5 cm, has the ability to reach the near-surface areas of the objects. The L band wavelength with a range from 15 to 30 cm is especially suitable for the ground under the vegetation, etc. accessing such objects [51]. In this study, Sentinel-1 C band ($\lambda = 5.5$ cm, 5.404 GHz) images were used.

3.4.2 Polarization

The electromagnetic wave's polarization shows which way the electric field vector is moving. Polarizations can be horizontal (H), vertical (V), or both horizontal and vertical. The polarization combinations are VV, VH, HH, and HV. The first letter in the notations indicates the polarization of the transmitted radiation and the second letter indicates the polarization of the received radiation.

3.4.3. The Angle Of Incidence Of Reflected Signals

The angle of incidence is the angle between the normal of the received surface and the direction of the reflected signal. Increasing or decreasing the angle affects the backscatter value. The higher the angle of incidence, the smoother the surface appears, resulting in reduced backscatter and darker images. A decrease in the angle of incidence causes an increase in backscatter and therefore a lighter gray value [52].

3.4.4. The Effect Of Roughness And The Geometric Structure Of The Surface

Surface roughness is a parameter that determines the interaction of its energy with the ground surface. Surface roughness refers to the height differences of the object from the plane. If the height difference of the surface is smaller than the radar wavelength, the surface is perceived as smooth, but when the height difference reaches the wavelength, the surface is perceived as rough. Rough surfaces scatter incoming energy equally in all directions, and most of the scattered energy can be recorded by radar systems. As the scattered energy increases the pixel value, rough surfaces often appear in light tones. Smooth surfaces, on the other hand, reflect the incoming energy without scattering, and only a small amount of the sent energy can return to the sensor. For this reason, smooth surfaces often appear dark. For example, characteristic shape and geometrical differences in terrestrial surfaces increase the ratio of roughness. The amount and strength of the returning signals are detected at high levels of brightness. Sea and lake surfaces are calm and smooth environments apart from meteorological factors such as wind and precipitation. For this reason, the transmitted signals reflect properly in these regions and are not backscattered to the sensor. For this reason, they appear black and smooth on the radar image. But in windy weather, the geometry of the waves and the mobility of the surface increases the back reflection, the brightness increases, and as a result, light gray tones can be widely seen in a certain texture in the radar image. Surface backscattering is explained by the relationship between the wavelength of the transmitted electromagnetic energy and the surface roughness [53]. In remote sensing, the scattering angle and the angle of incidence are the same, because, in radar systems, the receiving antenna and the antenna sending electromagnetic energy are in the same place. For this reason, backscatter values are considered in remote sensing.

3.4.5. Moisture

The interaction of radar signals with the surface can vary depending on moisture and precipitation. Backscattering increases as the moisture content of the object increases, so surfaces such as soil and vegetation appear brighter when they are wet (moist) than when they are dry. When objects are dry, the surface appears smooth and radar energy can travel from the surface to the depths and appear dark, regardless of whether it is a homogeneous surface such as soil, sand and ice, or causing excessive backscatter such as vegetation, forest cover [13]. Sea and lake surfaces are excluded from this situation. Because these regions consist only of water and the signals reflect properly in these regions. For this reason, wetlands always appear darker than normal areas.

The coherence value, obtained from two different satellite images at different times, was also calculated using the same satellite images for this study. The coherence value is a black-and-white image that takes a value between zero and one. In the image, bright areas have high coherence which indicates the similarity of the two data and dark areas have low coherence which shows the changed areas.

The Sentinel-1 is one of the observation satellites mission of the Copernicus program within the European Union. It consists of the Sentinel-1A and Sentinel-1B constellations, which were sent into orbit in April 2014 and April 2016, respectively. Both satellites were launched into orbit from Soyuz rockets in Kourou, French Guiana [54]. The Sentinel-1 satellite has dual polarization, 12-day imaging frequency, and free product supply. Sentinel-1A and Sentinel-1B can be used to reduce the temporal resolution to 6 days in the equator. Sentinel-1 satellite is used in many different areas such as monitoring agricultural lands, detecting and tracking ships, monitoring the marine environment, and quickly mapping the area in case of natural disasters [55]. Sentinel-1 satellites are displayed in four reception modes at different processing levels given in Table 3.4. Radar images are available in two Level-1 products. Single Look Complex (SLC) data are the first level images after signal processing. In SLC images, each pixel consists of a real and imaginary number. On the other hand, Ground Range Detected (GRD) data has only amplitude information [13]. In this study, descending orbit, IW mode SLC process level radar images, VV and VH polarizations are used in the WGS-84 coordinate system.

Table 3.4: Sentinel-1 beam modes features [56].

Mode	Arrival Angle	Resolution	Strip Width	Polarization(H= Horizontal V = Vertical)
Stripmap (SM)	20-45	5 x 5 m ²	80 km	HH+HV, VH+VV, HH, VV
Interferometric Wide swath (IW)	29-46	5 x 20 m ²	250 km	HH+HV, VH+VV, HH, VV
Extra Wide Swath (EW)	19-47	20 x 40 m ²	400 km	HH+HV, VH+VV, HH, VV
Wave (WV)	22-35-35-38	5 x 5 m ²	20x20 km	HH, VV

In the study, 26 Sentinel-1 radar images from 2018 were used. There is a 6-day time difference between the dates. For each date, both VH and VV polarizations were used. Backscattering values of individual pixels were calculated from each image and coherence value was generated for each pixel value from the coherence images obtained from two separate images with a 6-day difference between them. Radar image acquisition dates are shown in Table 3.4. These dates include the leaf development stage of the sunflower plant and the dates until the harvest stage.

Table 3.5: Available SAR image dates

Satellite name	Image Date	Satellite Name	Image Date
Sentinel-1B	24 April 2018	Sentinel-1A	11 July 2018
Sentinel-1A	30 April 2018	Sentinel-1B	17 July 2018
Sentinel-1B	6 May 2018	Sentinel-1A	23 July 2018
Sentinel-1A	12 May 2018	Sentinel-1B	29 July 2018
Sentinel-1B	18 May 2018	Sentinel-1A	4 August 2018
Sentinel-1A	24 May 2018	Sentinel-1B	10 August 2018
Sentinel-1B	30 May 2018	Sentinel-1A	16 August 2018

Sentinel-1A	5 June 2018	Sentinel-1B	22 August 2018
Sentinel-1B	11 June 2018	Sentinel-1A	28 August 2018
Sentinel-1A	17 June 2018	Sentinel-1B	3 September 2018
Sentinel-1B	23 June 2018	Sentinel-1A	9 September 2018
Sentinel-1A	29 June 2018	Sentinel-1B	15 September 2018
Sentinel-1B	5 July 2018	Sentinel-1A	21 September 2018

4. METHODOLOGY

In this part of the study, the process steps performed in the study are explained in order and the workflow of the study is given in Figure 4.1. The pre-processing steps

of Sentinel-1 satellite images and the pre-processing steps to create coherence images are also explained in detail. In addition, the working principle and features of the ANN method used in the study are mentioned.

In the study, first, vegetation indices were produced using Sentinel-2 optical images. Since Level-2A of Sentinel-2 images are used in the thesis, no pre-processing step has been applied. In the SNAP program, reflectance values were obtained from the sunflower plots opened on the index image. The reflectance values of the sunflower parcels were calculated separately for each index for 48 sunflower parcels. By taking the average of the calculated reflectance values within the parcel borders, for each parcel single value was calculated for each index.

In the study, the reference yield values for each parcel were obtained from the farmers in the field by traditional methods [6]. Then, the correlation between the reference yield values and the reflection values was examined and the dates with the highest correlation were determined. After the 48 parcels were divided into 4 groups of 12 on these dates. Three linear function sets were used for a test set to be created. This is because each group is used as a test and four linear functions can be obtained. The yield of the sunflower plant on the dates with the highest correlation was estimated by SLR and ANN methods and then compared with the reference yield values.

As a second step, the pre-processing steps of Sentinel-1 satellite images were made and the images were improved. The SNAP program was used to perform the pre-processing steps. 48 sunflower parcels were opened on the processed images and backscatter values were determined separately for each parcel on the dates determined in this way. The parcel image values were calculated by taking the average of the backscatter values of 48 parcels calculated separately for each date. Then, the correlation between the backscatter values and the reference yield values was examined. On the dates of the highest correlation, 48 parcels were divided into 4 groups of 12 each, and three linear function sets were used for a test set to be created. Then, the processed Sentinel-1 satellite images were divided into pairs with a 6-day time difference between them, and coherence images were created after the pre-processing steps. The coherence values of 48 parcels were calculated for each date from the created coherence images. The dates with the highest correlation were also divided into 4 groups of 48 parcels of 12 each. Three

linear regression function sets were used for a test set to be created. Then, yield estimation was made using SLR and ANN methods and compared with the reference values.

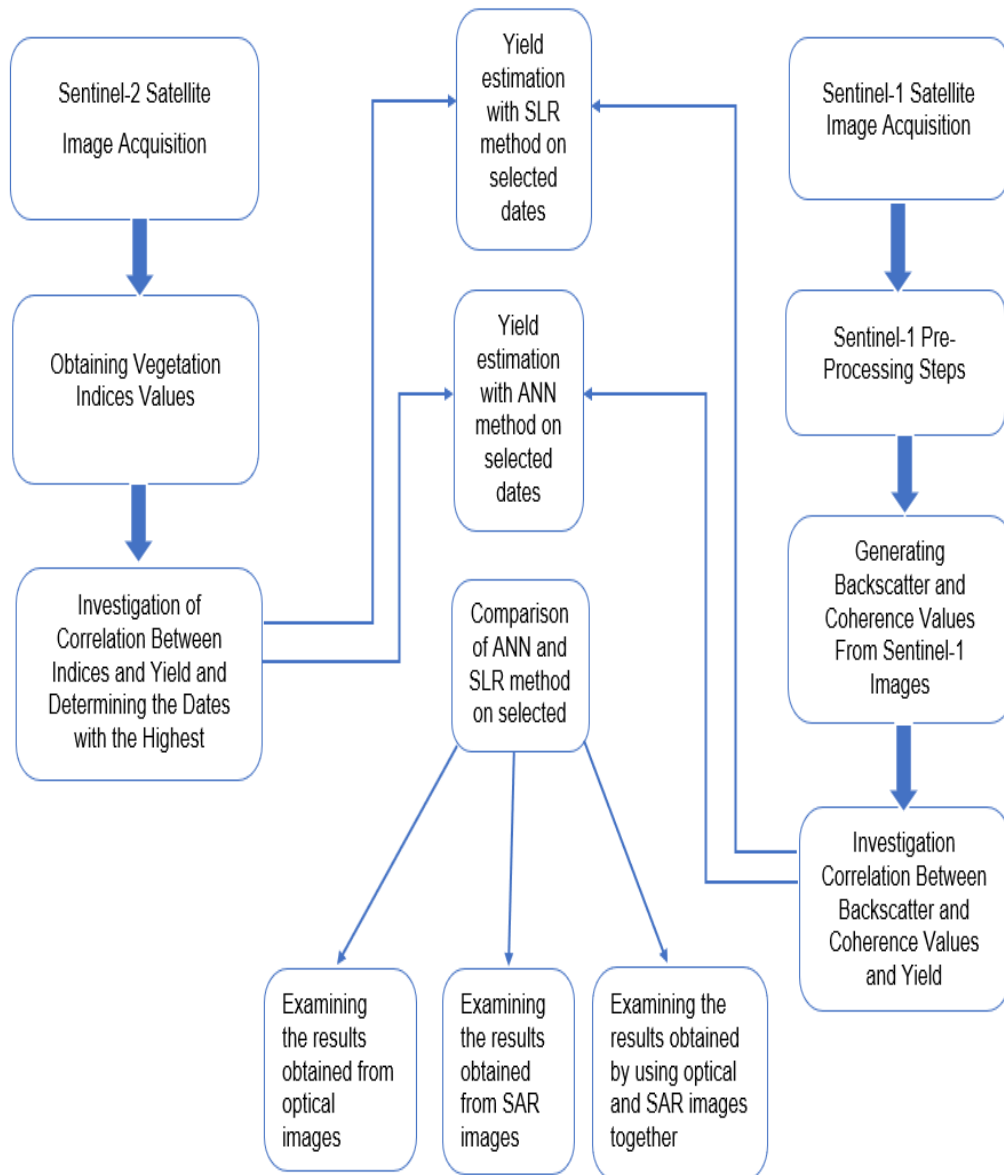

Figure 4.1. Workflow chart for this study.

4.1 Data Pre-processing

Satellite images contain systematic or unsystematic errors in their structure. Therefore, they need some fixes before they can be used in an application. These processes are generally defined as pre-processing steps. Because these processes form the basis for obtaining information from images in the next steps and are performed before the 'image processing and analysis steps. The pre-processing steps include geometric correction, which ensures geographical compatibility between the satellite image and the measured information, and radiometric correction, which aims to eliminate reflections that are not representative of the object in the detected image. Geometric Correction is the processing step of removing the effects of geometric distortion in the satellite image and fitting the image to a defined geographical location. The point coordinates in the image to be corrected are defined by the coordinates of the ground control points, such as latitude and longitude. This process is called rectification. Matching the same points of two images or correcting one image according to the other is called geometric registration. Radiometric Correction is the process that eliminates the atmospheric effects that cause false perceptions in the satellite image and makes the objects detected by the sensors prominent. Electromagnetic radiation signals coming from the sun and detected by the satellite detector after hitting the earth, undergo change due to gases and aerosols in the atmosphere as they pass through the atmosphere, so it is necessary to calibrate the image by applying some pre-processing steps to the image. This is called the atmospheric effect [57]. The preprocessing steps of the coherence image production from the SLC level of Sentinel-1 data were described below and shown in Figure 4.2.

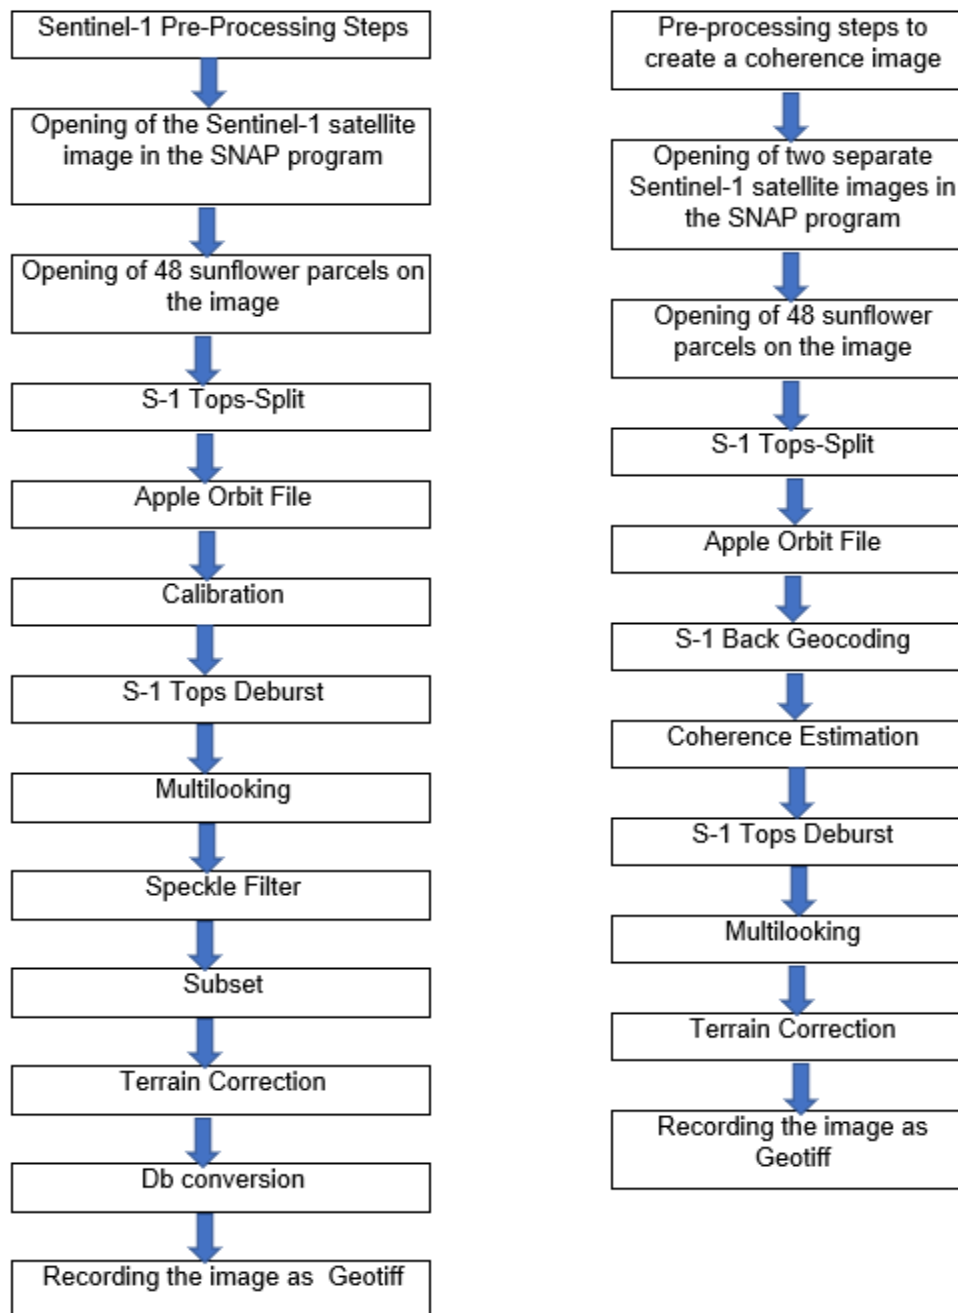

Figure 4.2 Sentinel-1 backscatter and coherence pre-processing

S-1 Tops-Split

First of all, because the SLC satellite image size is big, the area covering 48 sunflower parcels was selected with the help of Google Earth. The area to be studied has been cropped to a smaller size.

Apple Orbit File

Apply orbit file module was used to eliminate orbital errors of the image and to perform precise orbital calibration. This step allows for accurate image geocoding using the trajectory files contained in the metadata of each product [58].

Calibration

Calibration can be impaired in images taken under the influence of space conditions. The purpose of this step is to remove the complexity from the SAR data so that the values of pixels can be directly attributed to backscattering [59]. In this step, VH and VV polarization are used together. Outputsigma0 and outputbeta0 band types were selected and the next step was taken.

S-1 Tops Deburst

This step is done to integrate the data and the workspace is prepared. Burst images from all subscales of the image are resampled. Therefore, it is a necessary step.

Multilooking

This processing step is done to reduce the multiple views in the image that deteriorate under space conditions. This step, which is done to make the image clearer, increases the radiometric resolution and reduces the spatial resolution [60]. As a result of this process, a less noisy image is obtained. Therefore, it is a necessary step to take. This step has been applied for bands in both VH and VV polarization. It has been selected as the Number of Range Looks 4. It was selected as the Number of azimuth looks 1. The average number of ground resolution square pixels was taken as 14.33 m.

Single Product Speckle Filter

Spots on the satellite image are caused by the salt and pepper noise that occurs as a result of random constructive and destructive interference throughout the image [13]. In this study, the image was first subjected to multi-look processing and then the Refined Lee filter was applied to reduce speckles. The Refined Lee filter preserves the edges while averaging the satellite image. The filter takes into account the Local Linear Minimum Mean Square Error (LLMMSE) estimation

within edge-aligned windows, providing better preservation of details in an image [61]. The image on each date was then cropped at the same coordinates to cover the workspace.

Range Doppler Terrain Correction

In the Terrain Correction step, natural geometric distortions (i.e. foreshortening, overlapping, and shadow) in the SAR image are corrected using the digital elevation model (DEM) and image geocoding is performed [62]. Geocoding converts the range geometry of the image to the coordinate system of a map. Land geocoding; requires the use of a DEM to correct for local SAR geometric distortions [63]. In this process step, the bilinear interpolation method was used and the pixel size was sampled to a 10 m X 10 m spatial resolution. CDEM was used as DEM. SAR geometric distortions have been corrected and the image has been geocoded. After this process step, the pixel digital values in the obtained bands were converted to radar backscatter (dB) values. The formula used for this transformation is given in Equation 1. With this logarithmic transformation, the back reflection coefficients that do not have a unit value are converted to dB values [64].

$$\beta_{db}^0 = 10 * \log_{10}(\beta^0) \quad (1)$$

With these operations performed separately for each image date, the backscatter values of 48 parcels were calculated in both VH and VV polarization for each date. The image was recorded in GeoTIFF format and the image was made ready. After these pre-processing steps were performed, the backscatter values were calculated separately in both VH and VV polarization for each date and each parcel based on the images that were made ready. In order to produce coherence images from Sentinel-1 satellite images from two different times, Sentinel-1 satellite images of 26 different dates were divided into pairs with a 6-day time difference between them. Display dates divided into groups are shown in Table 2.8.

S-1 Back Geocoding

This step was applied one by one to group images to combine images from two different dates with orbit corrected and cropped to obtain a single image. In this step, SRTM 3Sec was used as the DEM. Bilinear interpolation was used as the resampling method. Then, these processes were printed and a stack image was obtained.

Coherence

At this stage, this process step was carried out to make coherence estimation from the stack image pairs. The coherence range size is selected as 10, coherence azimuth size is selected as 3. DEM was not changed, again SRTM 3Sec was chosen and other parameters were used without changing. In order to improve the coherence of images created after this processing step, the deburst, multilooking and terrain correction processing steps used to improve the Sentinel-1 images were applied to these images without changing the previously used parameters and the images were improved. Coherence values from these images covering the same area and 48 sunflower parcels were calculated separately for each parcel in both VH and VV polarization.

Table: 4.1: Image dates to calculate coherence value

24 April- 30 April 2018	5 July- 11 July 2018
30 April- 6 May 2018	11 July- 17 July 2018

4.2. Artificial Neural Network

ANN method is a learning method, that can produce new information, create new information, and automatically make predictions without any assistance. ANN

consists of artificial cells connected to each other. It is accepted that these cells are connected and each connection has a value. The most basic task of the ANN is to predict an output set that corresponds to an input set shown to it. The high accuracy of this estimated output set is the most important feature of ANN. An ANN consists of three layers. These; are the input layer, hidden layer and output layers. The visual figure containing the layers and connections of the neural network is shown in 4.2.1. The input and output layers contain nodes corresponding to the input and output variables, respectively. The number of hidden nodes determines the number of connections between inputs and outputs and may vary depending on the particular problem. If too many nodes are used, then the ANN can be overtrained, causing it to memorize the training data, resulting in poor predictions [65]. Therefore, the number of hidden layers and the number of neurons in the hidden layer can only be decided by a trial because this method is a trial and error method.

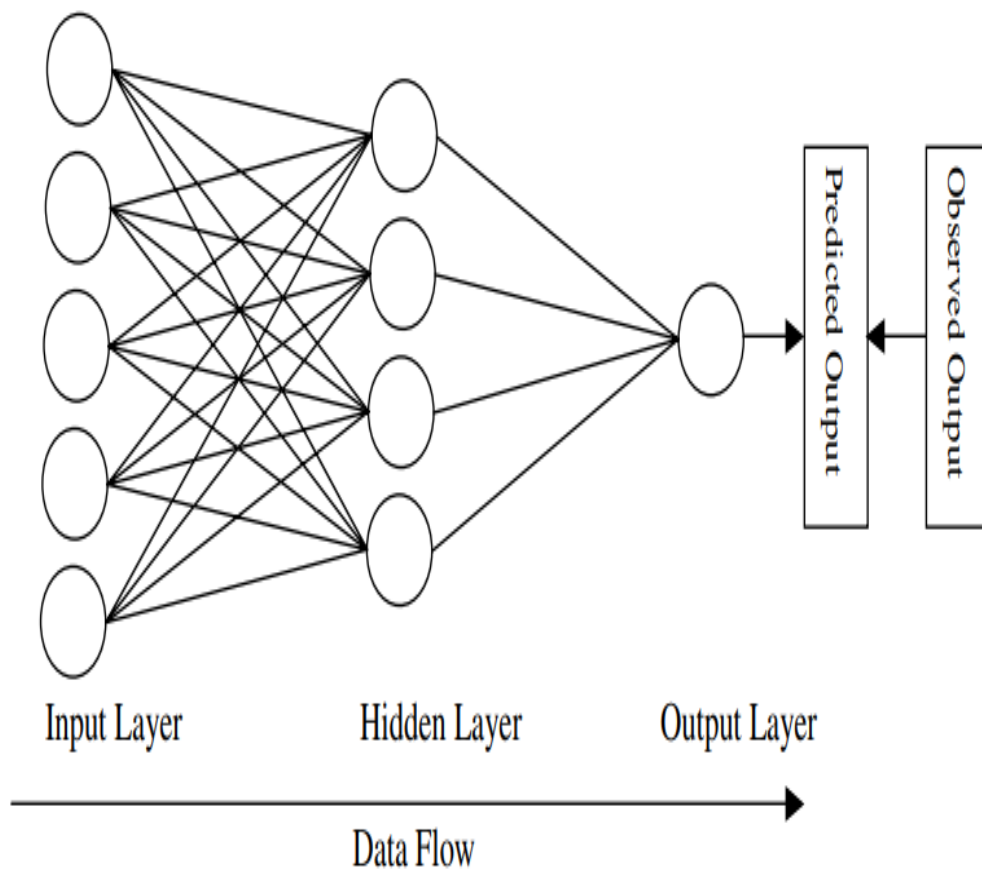

Figure 4.3. Layers and connections of an artificial neural network

It is the basic principle to determine various input and output parameters in yield estimation with ANN. In this study, the MATLAB program was used when making transactions with ANN. 36 parcels of 48 sunflower parcels were used as input parameters. As an output parameter, the previously determined reference yield values of the same parcels were also used. Then, the parcels were divided into groups among themselves and decoupled as test and training data respectively, and accuracy analyses were applied to all parcels.

5. RESULTS

5.1. Results of Optical Data

In the study, the phenological stages of the sunflower plant were identified using vegetation indices derived from Sentinel-2 data. The average reflection of the 48 parcels graph for the four indices studied is shown in Figure 5.1.

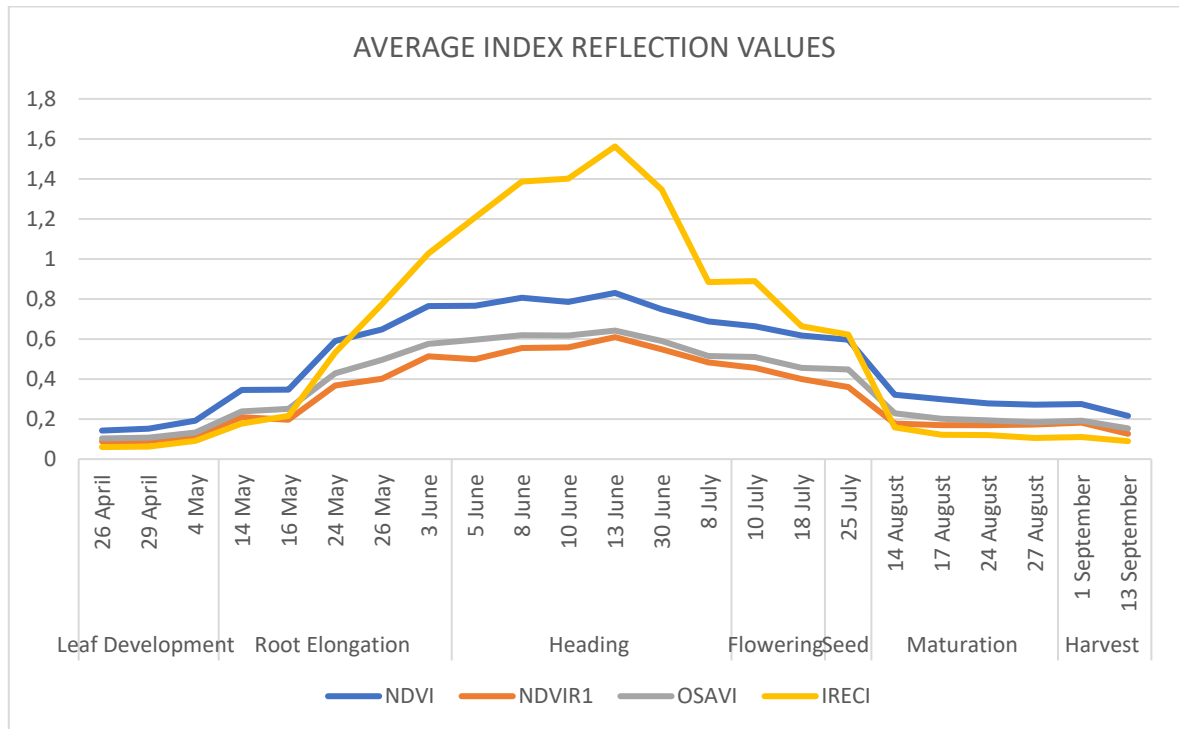

Figure 5.1. Reflection values of the indices for the 48 parcels

According to Figure 5.1, it was observed that the reflectance value of the sunflower plant increased in all four indices from the end of April to the middle of June. From the end of June to September, a decrease was observed in the reflectance values. The month of June, when the reflectance value increases, covers the first stage before flowering occurs.

The correlation between the reflectance values and vegetation indices obtained from 23 satellite images taken from Sentinel-2 satellites and the predetermined reference yield values obtained from the field was examined for 48 parcels. The correlation between reference yield and indices is given in Figure 5.2. Looking at the correlation for the four indices examined, it was determined that the dates with

the highest correlation were 30 June, 8 July, and 10 July. For these dates, the highest correlation is given in Table 5.1.

Figure 5.2. Correlation values between reference yield and indices.

Table 5.1: Correlation values between reference yield values and indices on 30 June, 8 July, and 10 July 2018. The highest correlation values date is shown in red and the lowest correlation values are in blue for each date.

	30 June 2018	8 July 2018	10 July 2018
NDVI	0,876	0,749	0,756
NDVIR1	0,882	0,792	0,796
OSAVI	0,879	0,772	0,762
IRECI	0,875	0,783	0,760

In the study, the yield was first obtained from the reflectance values of the indices using the SLR. RMSE values were calculated for each index on 30 June, 8 July, and 10 July. Calculated RMSE and average RMSE for each group are given in Figure 5.3.

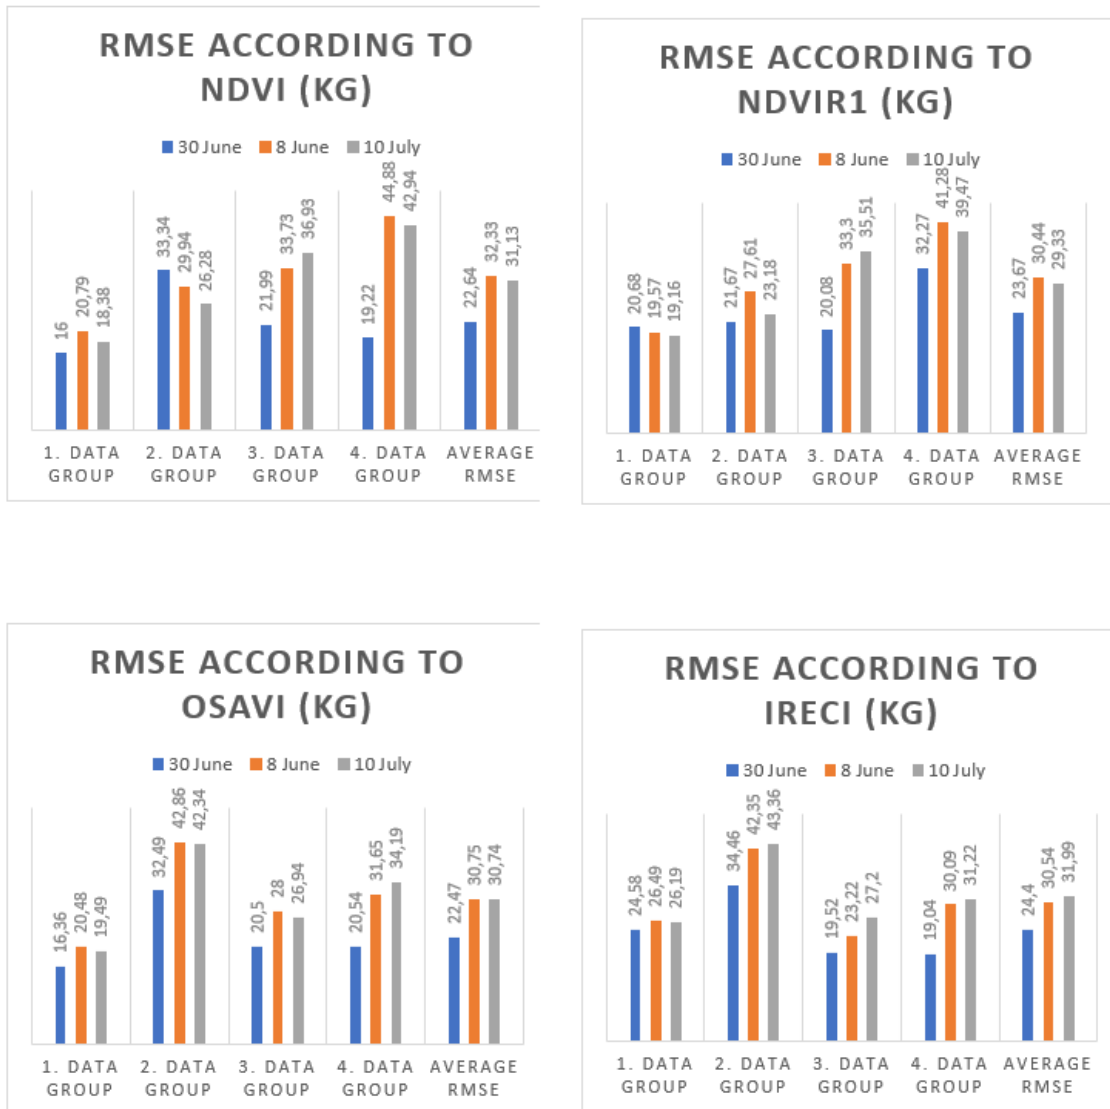

Figure 5.3. RMSE of each data and average RMSE values were calculated using the SLR method.

Looking at the average of RMSE values, in the SLR, the OSAVI gave the best result for the date of 30 June (Figure 5.3). NDVIR1 gave the best result for 8 July. The index that gave the best results for July 10 was again the NDVIR1. ANN method was used as the next step and yield values were obtained with this method. The yield values obtained by these two different methods were compared with the reference yield values. Details are given in the appendices [Appendix A]. In the ANN method, firstly, each index value was processed separately for each group as a single input. The number of inputs is taken as 1. The output number is taken as 1. The number of iterations was determined as 1000. The number of hidden layers was tried by trial and error method and different combinations were tried

and the value that gave the best result was taken as the basis. The number of hidden layers and RMSE selected when used indices are processed as inputs alone are given in Table 5.2. The lowest error values for each date are shown in bold.

Table 5.2: The number of hidden layers and RMSE selected when indices are used as input values alone.

30 June NDVI		8 July NDVI		10 July NDVI

When each index value is processed as a single input, the calculated RMSE for each group and the average RMSE on 30 June, 8 July, and 10 July are given in Figure 5.4.

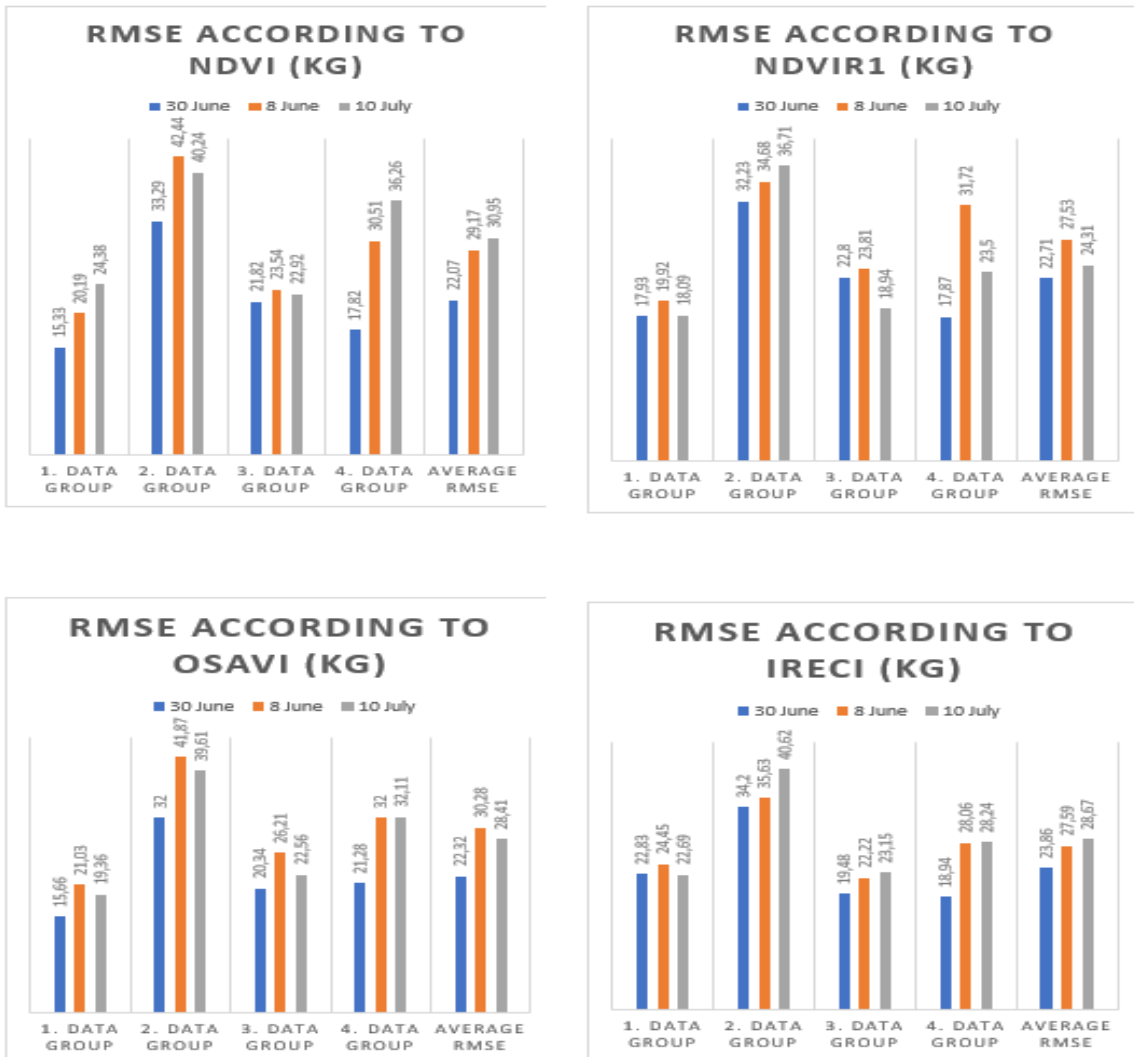

Figure 5.4. RMSE of each data and average RMSE values were calculated using the ANN method.

When examining the average RMSE values, in the ANN method, on June 30, the NDVI gave the best results. The index that gave the best results on July 8 and 10 was the NDVIR1 (Figure 5.4). When all indices are examined together, the RMSE calculated for each group in SLR and the average RMSE are given in Figure 5.5.

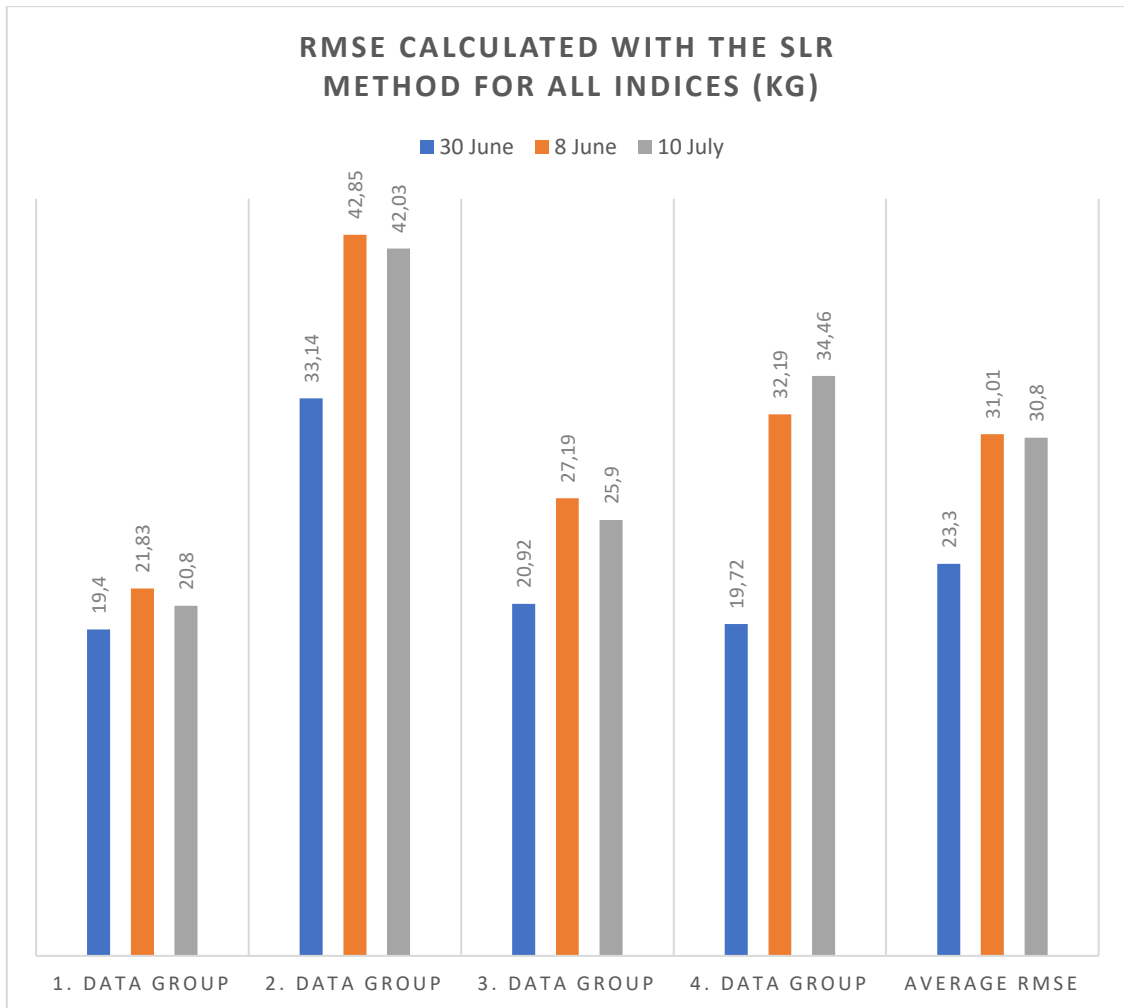

Figure 5.5. RMSE and average RMSE values were calculated using the SLR method.

When all indices were used together as input values, the yield obtained by RMSE, SLR method, and yield values produced by ANN were estimated and analyzed separately for 4 groups for the three dates examined. These results are given in the appendices in detail [Appendix B]. A separate ANN model was created for each examined date. The number of inputs is taken as 4 and the number of outputs as 1. The number of iterations was determined as 1000 without changing it. The number of hidden layers was tried according to the number of entries for each date and the value that gave the best result in different combinations was taken. In Figure 5.6, the ANN model created on June 30, the date that gave the best result in this step, is given as an example.

The number of hidden layers and RMSE selected when used indices are processed together as input are given in Table 5.3. The lowest error values for each date are shown in bold. The results of this experiment are given in Figure 5.7.

Figure 5.6. ANN model was created by using 4 indices together on 30 June.

Table 5.3: The number of hidden layers and RMSE selected when all indices values are used together as input values

30 June NDVI		8 July NDVI		10 July NDVI	
Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE
5	22,13	5	27,81	5	28,63
6	21,59	6	28,64	6	30,55
7	22,36	7	26,93	7	31,79

Figure 5.7. RMSE and average RMSE values were calculated using the ANN.

When the graphs in Figure 5.5 and Figure 5.6 were examined, the ANN method gave better results than the SLR in all groups on all 3 dates studied, when all indices were processed together as input values. The best results were obtained during the heading period of the sunflower plant on June 30.

5.2. Results of SAR Data

After, the preprocessing steps the backscatter values of 48 parcels were determined for each date in both VH and VV polarization. As with optical images, the average correlation between reference yield values and backscatter values and RMSE were examined over the produced backscatter values. The average values of the backscatter of 48 parcels for each polarization (VH and VV) are given in Figure 5.8.

Figure 5.8. Average backscatter values between reference yield and polarization.

Considering the backscatter values, the highest backscatter value was observed in the 30 May root elongation phase in VH and VV polarization. Afterward, a fluctuating decrease and then an increase in the backscatter value were observed in two polarizations, and it was determined that the values remained constant during the harvest period.

In order to compare optical and SAR images in the further step, the SAR image dates closest to 30 June, 8 July, and 10 July, which were determined as the highest correlation dates in optical images, as selected. These image dates are June 29, July 5, and July 11. The correlation between the backscatter values and the predetermined reference yield values was examined for both VH and VV polarization in 48 parcels. Correlation values between reference yield and backscatter values for these dates are given in Table 5.4.

Table 5.4: Correlation values between reference yield values and backscatter values for 29 June, 5 July, and 11 July 2018

	29 June 2018	5 July 2018	11 July 2018
VH	0,039	-0,027	-0,008
VV	0,114	0,030	0,072

It was observed that the correlation values in the VV polarization were higher than the correlation values in the VH polarization within the three dates discussed. It was determined that the date with the highest correlation in both polarizations was June 29 (Table 5.4). The yield was first obtained by backscattering values from the linear regression function. RMSE values were generated on selected dates for each polarization. By the SLR method, 48 plots were divided into 4 groups of 12 for the dates of 29 June, 5 July, and 11 July. Three sets of linear regression functions were used for a test set to generate. The calculated RMSE and average RMSE for each group in both VH and VV polarization are given in Figure 5.9.

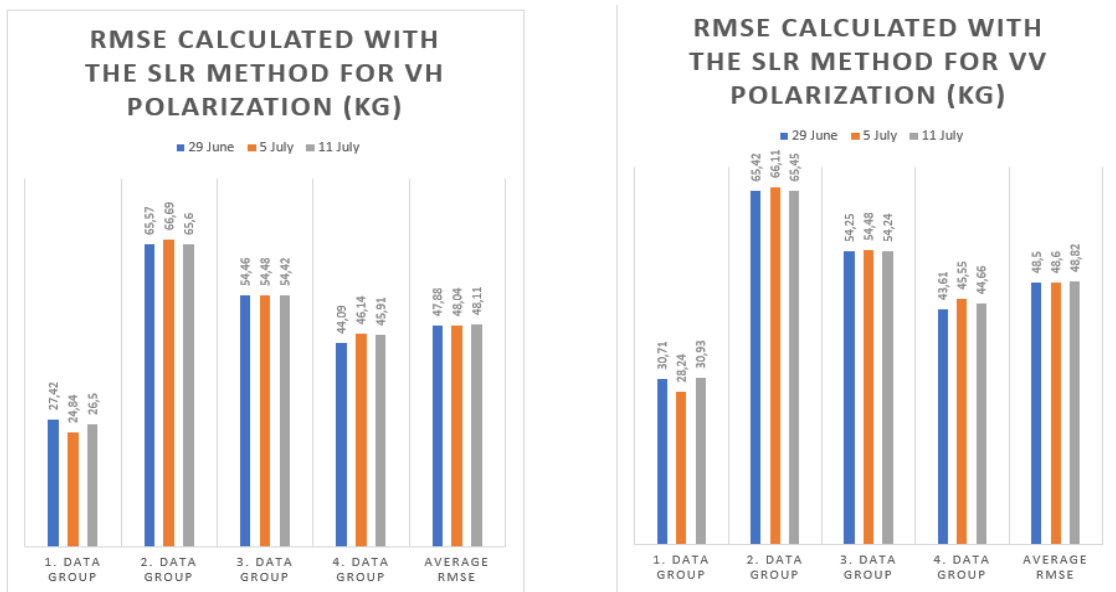

Figure 5.9. RMSE and average RMSE for backscatter values in the SLR method.

Looking at the average RMSE values over the three dates, the SLR method gave better results for VH polarization than for VV polarization (Figure 5.8). ANN method was used as the next step and yield values were obtained with this method. The yield values obtained by these two different methods were compared with the

reference yield values. The results are detailed in the appendices [Appendix C]. In the ANN method, firstly, the backscatter values were processed as a single input on the selected dates for each group. The number of inputs is taken as 1 and the number of outputs as 1. The number of iterations was determined as 1000. The number of hidden layers was tried by trial and error method and different combinations were tried and the value that gave the best result was taken as the basis. The number of hidden layers and RMSE selected when used backscatter values are processed as inputs alone are given in Table 5.5. The best result for each date is shown in bold.

Table 5.5: The number of hidden layers and RMSE selected in the VH and VV polarization when the backscatter values alone are used as input values.

29 June Backscatter(VH)		5 July Backscatter (VH)		11 July Backscatter (VH)	
Hidden Layer No	Average RMSE	Hidden Layer No	Average RMSE	Hidden Layer No	Average RMSE
2	45,6	2	47,4	2	48,07
3	47,61	3	48,49	3	49,9
4	47,54	4	48,88	4	50,05
5	45,98	5	48,73	5	50,55
29 June Backscatter(VV)		5 July Backscatter (VV)		11 July Backscatter (VV)	
2	45,65	2	46,21	2	48,09
3	42,46	3	48,9	3	49,81
4	44,47	4	48,42	4	51,65
5	43,21	5	49,39	5	51,23

The calculated RMSE and average RMSE for each group in both VH and VV polarization are given in Figure 5.10.

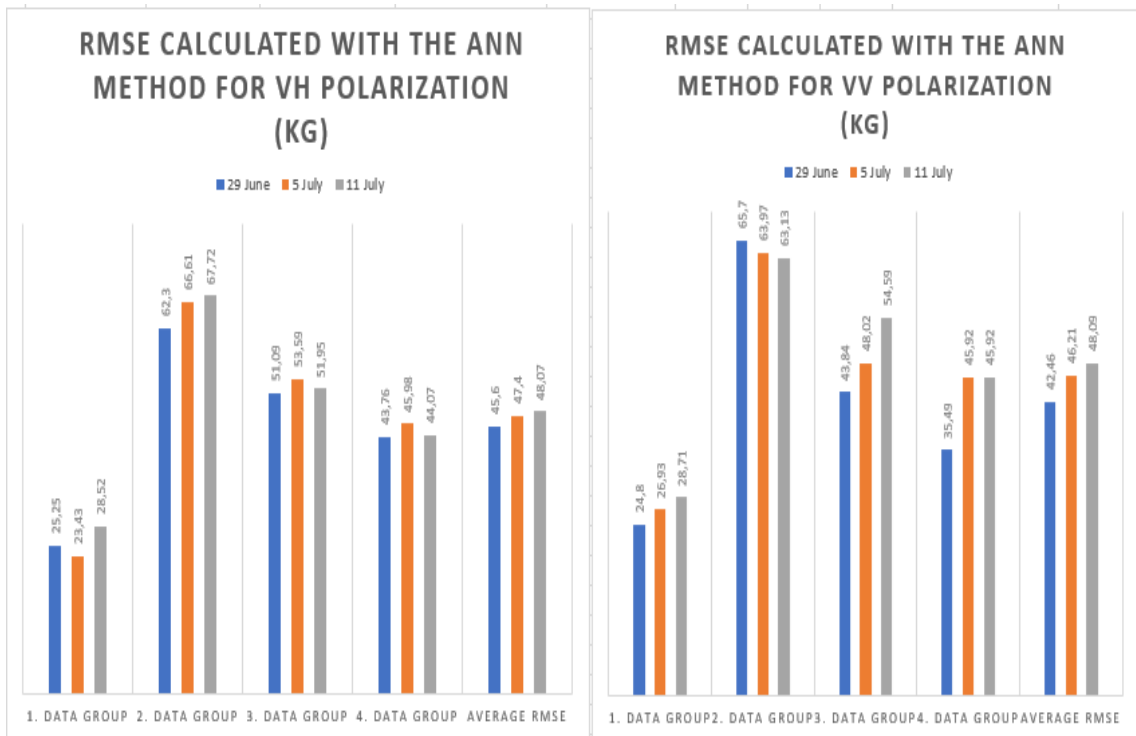

Figure 5.10. RMSE and average RMSE for backscatter values in the ANN method.

Considering the average RMSE values on June 29 and July 5 and using the backscatter values alone as the input value, VV polarization gave better results than VH polarization. On July 10, there is little to no difference between VH and VV polarization (Figure 5.9).

In order to produce coherence values from two different SAR satellite images at two different times, satellite images from 26 different dates were divided into pairs in two polarizations with a 6-day time difference between them. The average coherence value graph obtained from these grouped views is given in Figure 5.11.

Figure 5.11. Average coherence values of the polarizations.

In both polarizations, the highest coherence value was observed between April 24 and 30, and a significant decrease in coherence values was observed during the leaf development phase. It was observed that the values remained constant in the phase from root elongation to seed maturation, increased during the ripening period, and started to decrease again in the harvest period.

In order to compare the yield values we obtained using optical and SAR images in the further step, the SAR image date ranges closest to 30 June, 8 July, and 10 July, which are determined as the highest correlation date in optical images, are 29 June - 5 July, 5 July - 11 July, and 11 July-17 July were selected and the correlation between the coherence values and the predetermined reference yield values was examined for VH and VV polarization in 48 parcels.

When examining the correlation between the coherence values and the reference yield, it was seen that the correlation in VH polarization was higher on the pair of 29 June - 5 July (Table 5.6). It was seen that the correlation in the VV polarization was higher than the VH polarization in the image dates of 5 July - 11 July and 11

July - 17 July. The highest correlation in VH and VV polarization is determined by the image date of July 5th to July 11th (Table 5.6).

Table 5.6: Correlations between reference yield and coherence values on 29 June- 5 July, 5 July-11 July, and 11 July - 17 July 2018

	29 June- 5 July 2018	5 July-11 July 2018	11 July-17 July 2018
VH	0,082	-0,128	0,081
VV	0,011	-0,278	0,099

The yield was obtained from coherence values by the SLR method using linear functions. RMSE values were produced at the selected dates for each polarization. For the dates 29 June - 5 July, 5 July - 11 July, and 11 July - 17 July, as applied previously, 48 parcels were divided into four groups of 12 each. It was used for one set of tests to generate three sets of linear functions. The calculated RMSE and average RMSE for each group in both VH and VV polarization are given in Figure 5.12.

Figure 5.12. RMSE and average RMSE for coherence values in the SLR method.

Considering the average RMSE values, VH polarization on 29 June - 5 July and 5 July - 11 July gave better results in the SLR method than VV polarization (Figure

5.11). On July 11-17, VV polarization gave better results in the SLR method than VH polarization.

While the yield was obtained with the ANN method, the coherence values were first processed separately for each group as a single input for three dates. The number of entries is taken as 1. The output number is taken as 1 again. The number of iterations is set to 1000 without changing it. The number of hidden layers was tried with different combinations by trial and error method and the value that gave the best result was taken. The number of hidden layers and RMSE selected when used coherence values are processed as inputs alone are given in Table 5.7. The best result for each date is shown in bold.

Table 5.7: The number of hidden layers and RMSE selected in the VH and VV polarization when the coherence values alone are used as input values.

29 June-5 July Coherence (VH)		5 July-11 July Coherence (VH)		11 July-17 July Coherence (VH)	
Hidden Layer No	Average RMSE	Hidden Layer No	Average RMSE	Hidden Layer No	Average RMSE
2	49,03	2	48,19	2	51,32
3	47,17	3	50,4	3	50,16
4	54,65	4	47,22	4	53,76
5	52,86	5	48,02	5	51,59
29 June-5 July Coherence (VV)		5 July-11 July Coherence (VV)		11 July-17 July Coherence (VV)	
Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE
2	48,76	2	46,24	2	46,51
3	53,01	3	47,28	3	48,87
4	47,62	4	47,96	4	50,03

RMSE values were calculated from the yield values estimated by the ANN method. The estimated yield values and reference yield values were compared for both polarizations by SLR and ANN methods and examined. Details are given in the appendices [Appendix D]. Calculated RMSE and mean RMSE for each group in both VH and VV polarization are given in Figure 5.13.

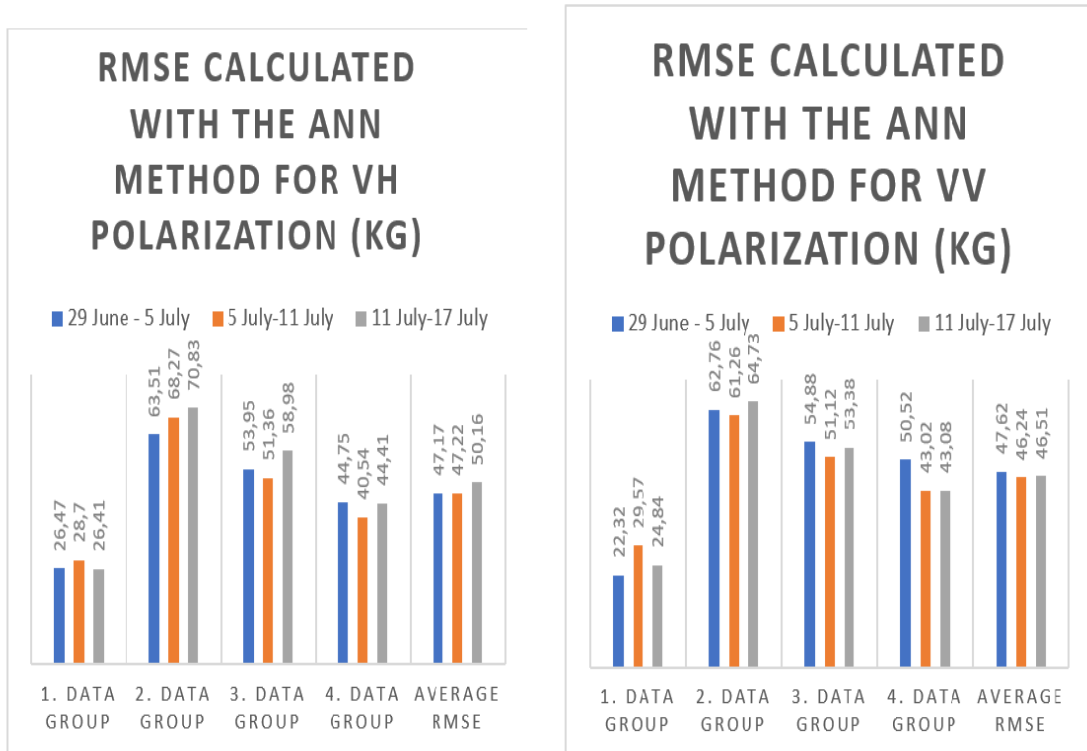

Figure 5.13. RMSE and average RMSE for coherence values in the ANN method.

Considering July 5-11 and July 11-17 coherence data as input values alone, the VV polarization in the ANN method has given better results than the VH polarization comparing the average error (Figure 5.12).

When the backscatter and coherence values are used as input values alone, better values have been obtained from VV polarization compared to VH polarization in the ANN method for the most part. For this reason, when backscatter and coherence values are used together as input values in the ANN method, VV polarization is taken into account after this stage. As an introduction, only VV polarization was used for both backscatter and coherence values. The number of inputs is taken as 2 and the number of outputs as 1. The number of iterations was

taken as 1000 without changing, yield and RMSE was calculated. Details are given in the appendices [Appendix E].

According to the number of entries for each date, the number of hidden layers was tested with different combinations, and the value that gave the best results was taken. When backscatter and coherence are processed together as input, the number of hidden layers and the selected RMSE is given in Table 5.8. The best result for each date is shown in bold.

Table 5.8: When the backscatter and coherence values are used together as the input value, the selected hidden layer number and RMSE

29 June-5 July (VV)		5 July-11 July (VV)		11 July-17 July (VV)	
Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE
3	47,81	3	47,56	3	50,54
4	44,56	4	47,22	4	48,52
5	46,73	5	48,12	5	50,66
6	45,37	6	48,76	6	49,9

When backscatter and coherence are examined together, the calculated RMSE and mean RMSE for each group in both SLR and ANN methods are given in Figure 5.14.

Figure 5.14. RMSE and Average RMSE for coherence and backscatter for VV.

5.3 Results of Optical and SAR Data

In this process step, NDVI, NDVIR1, OSAVI, and IRECI vegetation indices produced from optical satellite images and backscatter and coherence of VV polarized SAR images were used together as input values in the ANN method. The dates were analyzed as 29 June-5 July, 5-11 July, and 10-17 July to include both optical image dates and SAR satellite image dates. The number of iterations is taken as 1000, unchanged. The number of inputs is taken as 6 and the number of outputs as 1. The number of hidden layers, again according to the number of inputs, many different combinations were tried and the value that gave the best result was taken into consideration. When NDVI, NDVIR1, OSAVI, and IRECI, backscatter, and coherence values are used together as inputs, the number of hidden layers and the selected RMSE are given in Table 5.9. The best result for each date is shown in bold.

Table 5.9: The RMSE of the selected number of the hidden layer when SAR and optical image values are used together.

29 June-5 July (VV)	5 July-11 July (VV)	10 July-17 July (VV)

Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE	Hidden Layer Number	Average RMSE
7	28,87	7	35,21	7	32,44
8	26,83	8	33,49	8	31,04
9	29,9	9	35,36	9	33,56
10	28,54	10	34,75	10	33,98

When the data produced from optical and SAR satellites are examined together, the calculated RMSE and average RMSE for each group in both SLR and ANN methods are given in Figure 5.15. Details are given in the appendices [Appendix F].

Figure 5.15. RMSE and Average RMSE for optical and SAR.

6. DISCUSSIONS

In the study, first of all, using the index reflectance values obtained from the optical images, the yield estimation study was carried out by SLR and ANN methods and the RMSE was calculated. When the indices are used separately as a single input value, it was noticed that the ANN method gave better results than the SLR method in all three dates examined. Estimated values are given in Table 6.1 for the three dates examined. In the ANN method, NDVI gave the best result on June 30. NDVIR1 gave the best results on 8 and 10 July. However, in the SLR method, the index that gave the best result on June 30 was OSAVI. It was seen that OSAVI produced a better value than NDVI in the SLR method, but NDVI contributed more than OSAVI in the ANN method. As a result, it was concluded that the contribution of the indices may vary according to the method used in yield estimation studies, and in this study, the best estimation study was made in the ANN in the NDVI and NDVIR1 indices.

Table 6.1: The Average RMSE of the indices calculated by SLR and ANN methods.

	NDVI	NDVIR1	OSAVI	IRECI
30 June Average Linear RMSE	22,64	23,67	22,47	24,40
30 June Average ANN RMSE	22,07	22,71	22,32	23,86
8 July Average Linear RMSE	32,33	30,44	30,75	30,54
8 July Average ANN RMSE	29,17	27,53	30,28	27,59
10 July Average Linear RMSE	31,13	29,33	30,74	31,99
10 July Average ANN RMSE	30,95	24,31	28,41	28,67

Similar to this study, G. Narin et al. (2021) investigated the relationship between the NDVI and NDVIR1 indices produced from the Sentinel-2 data. They examined SLR, CNN, and ANN methods together with the use of indices and estimated the yield of the sunflower plant. They stated that they obtained the best estimation results in the NDVI and the CNN technique with the RMSE of 20,87 Kg/da on 30th June 2018. They stated that there was not much superiority between the NDVI and NDVIR1 indices. Likewise, in this study, NDVI gave the best result with 22.07 Kg/da on 30 June in the ANN method. On June 30, it was observed that there was not much superiority between the NDVI and NDVIR1 indices. In addition, combining multispectral and SAR features did not improve the result. In another study, Abdikan et al. (2022) used SLR and ANN methods while determining the crop height of sunflowers utilizing both Sentinel-1 SAR and Sentinel-2 satellite images. In conclusion, they stated that NDVIR1 provided more contribution than the image of NDVI from their previous studies. This shows the result that not only the method but also the contribution of the indices can change according to the subject studied.

When 4 indices are processed together as input values, the ANN method again gave better results than the SLR method. The best yield estimate was made on June 30, when all indices were used together as input values, In Figure 6.1, the difference between the reference yield values of 48 parcels and the estimated yield values is shown by Decolorizing from light to dark. The best performing parcels are shown in the darkest color, while the worst performing parcels are shown in the lightest color. There may be many different reasons why some parcels in the same area produce good value and some parcels produce bad value. The reason for this may be that the soil type is different, the necessary nutrients and needs are not met, less irrigation is performed, or the October area is kept narrow.

When Figure 6.1 is examined, for example, small parcels such as 23 and 24 produced poor yield values, but large parcels such as 21 and 29 produced better values. However, not all small-sized parcels produced bad values, and not all large-sized parcels produced good values. For this reason, a relationship could not be established between the parcel size and the difference yield values obtained from the parcel.

Figure 6.1. Difference (kg) between reference yield values and estimated yield values on 30 June.

It was concluded that using indices together as input in the ANN method reduces the error rate. The results obtained are given in Table 6.2. However, while estimating the yield with the ANN method and determining the number of hidden layers, many different combinations were tried and the number of hidden layers that gave the best results was taken as a basis. The process was repeated many times until the best value was found. Although this situation causes the ANN to memorize the data and work with the learned accuracy, it has been concluded that it is a method that can be used in determining the yield.

Table 6.2: The Average RMSE calculated by SLR and ANN method, when 4 indices are processed together as input value.

	Linear Average RMSE	ANN Average RMSE
30 June	23,30	21,59
8 July	31,01	26,93
10 July	30,80	28,63

Saranya and Nagarajan (2020) compared linear regression and the ANN model in their crop yield estimation study and as a result, they stated that corn and soybean have a higher correlation with the ANN model and give better results than linear regression. However, since the study focused on the estimation of agricultural crop yields using ANNs with good predictive results, they emphasized that research on processing noise in images requires to be explored, and optimization of models needs further investigation [66].

When the yield estimation is made using the backscatter values obtained from the SAR images, it is seen that the ANN method gives better results than the SLR method in both polarizations (VH, VV). The results are given in Table 6.3. However, when the indices were used, the sunflower plant made a better yield estimation. Backscatter values were not sufficiently effective when used alone in yield estimation.

Table 6.3: The Average RMSE of the backscatter calculated by SLR and ANN methods.

	Backscatter (VH)	Backscatter (VV)
29 June Average Linear RMSE	47,88	48,50
29 June Average ANN RMSE	45,60	42,46
5 July Average Linear RMSE	48,04	48,60
5 July Average ANN RMSE	47,40	46,21
11 July Average Linear RMSE	48,11	48,82
11 July Average ANN RMSE	48,07	48,09

Similarly, Fieusal et al. (2016) estimated the yield of maize crops by using the ANN method using Spot-4/5 and Formosat-2 optical and Radarsat-2 and TerraSAR-X microwave satellite images. They determined that the maize crop gave the best estimation result in the red wavelength, and the adaptation of the backscatter values remained lower in the yield estimation. However, they observed that the combination of backscatter and red reflection provided the accuracy of the yield estimation with $RMSE=7.0 \text{ q ha}^{-1}$ and $R^2= 0.69$. The combination of backscatter and red wavelength did not give the best results but gave acceptable accuracy.

In this study, the inability to obtain the desired yield estimation contribution from the backscatter values may be related to the angle between the normal surface and the reflected signal. This situation may have caused the desired values not to be produced from the backscatter values. The crop type, size, and shape of the plant may contribute to the backscatter value. Additionally, the water content and biomass of the crops with broad leaves also influence the response of energy [67]. The behavior of the backscatter values does not show a trend as indices derived from optical data. The backscatter has an increasing trend, with an up-and-down behavior from leaf development to the heading period. the backscatter of VV is stable to the end of seed phenology and then decreases to the harvest. The backscatter of VH decreases slowly from the end of root elongation to the harvest time (Figure 5.8).

The coherence also showed stable behavior from the root elongation to the end of seed phenology In both VV and VH polarimetry which indicated the contribution of polarimetry is limited and for the four phenology coherence is almost stable, and it is difficult to discriminate the phenology. Only in the maturation period, there is a difference and VV provided higher coherence than VH data (Figure 5.11). When estimating the yield using the coherence values obtained from the SAR images, it was concluded that the ANN method provided better results than the SLR method in both polarizations (VH, VV). It has been determined that the coherence values cannot be used alone in the estimation of yield, the accuracy of the results is below 70% and the error rates are high. The results are given in Table 6.4.

Table 6.4: The Average RMSE of the coherence calculated by SLR and ANN method.

	Coherence (VH)	Coherence (VV)
29 June - 5 July Average Linear RMSE	47,19	47,76
29 June - 5 July Average ANN RMSE	47,17	47,62
5 July- 11 July Average Linear RMSE	47,23	48,51
5 July- 11 July Average ANN RMSE	47,22	46,24
11 July- 17 July Average Linear RMSE	50,18	48,01
11 July- 17 July Average ANN RMSE	50,16	46,51

While yield was estimated by the ANN method using backscatter values and coherence values, VV polarization gave better results than VH polarization in most of the studied dates. Therefore, when backscattering and coherence values were used together, only VV polarization was considered at this stage. Similarly, Amherdt et al. (2022) investigated the contribution of backscatter and coherence values produced by the Sentinel-1 satellite to the mapping of corn and soybean. As a result, it was determined that VV polarization gave better results than VH polarization.

When the backscatter and coherence values are processed together as input values, ANN gave better results than the SLR method on 29 June-5 July and 5 July-11 July. However, on 11-17 July, the SLR method gave better results than the ANN method. The results are given in Table 6.5. While the use of backscatter and coherence values together reduced the error rate on 29 June-5 July, it did not affect the error rate much on other dates. The use of backscatter and coherence values together did not have a positive effect on yield estimation. It was concluded that adding coherence to the backscatter information in the VV polarization of the sunflower plant did not contribute to the yield estimation study.

Tablo 6.5: The Average RMSE calculated by SLR and ANN method, when backscatter and coherence values are processed together as an input value.

	Linear Average RMSE	ANN Average RMSE
29 June - 5 July (VV)	48,13	44,56
5 July-11 July (VV)	48,55	47,22
11 July-17 July (VV)	48,41	48,52

However, Amherdt et al. (2022) used 605 polygons (samples) from 49 Sentinel-1 satellite images for soybean and corn mapping and investigated the contribution of coherence value to backscatter value using the Random Forest method. They concluded that it might be a suitable tool. This may be due to the method they use and the large number of samples. This has shown that although the use of backscatter and coherence values together contributes in some cases, it does not contribute to the ANN method when estimating the yield and decreases the accuracy and increases the error rate. The reason for this may be the small number of parcels examined in the studied area, the different reactions of the examined plant species in different seasons, the method used, or the study area.

As a final step, the yield was estimated by using the indices, backscatter, and coherence values obtained from the optical and SAR satellite images together. The dates were set as 29 June - 5 July, 5 July - 11 July, and 10 July - 17 July, to cover both optical images and SAR satellite images. For all three dates, the ANN method gave better results than the SLR method. The results are given in Table 6.6.

Table 6.6: The Average RMSE calculated by SLR and ANN method, when indices, backscatter, and coherence values are processed together as input value.

	Linear Average RMSE	ANN Average RMSE
29 June - 5 July (VV)	31,57	26,83
5 July- 11 July (VV)	36,86	33,49
10 July- 17 July (VV)	36,67	31,05

The results show that using the Sentinel-2 optical satellite image and Sentinel-1 SAR satellite image together in the ANN method did not improve the yield

estimation (Table 6.6.). The use of backscatter and coherence values with indices did not reduce the error rate. However, an acceptable result was obtained. The yield estimated using only indices gave much better results. Similar to this study, Ameline et al. (2018) estimated the yield of maize plants using an agro-meteorological model with Landsat-8 optical satellite image and the Sentinel-1 SAR satellite image. As a result, they stated that the efficiency estimation was lower with the use of these two satellites together, but it could be considered an acceptable result. They commented that the use of SAR or optical data alone to enable maize monitoring is not sufficient due to the low sensitivity of the SAR signal to crop growth and the inability to obtain sufficient optical data due to the risk of cloud cover. They also argued that a new model should be included to simulate dry masses and yield.

The average RMSE calculated when optical images, radar images, and optical and radar images are processed together in the ANN method is given in Figure 6.1.

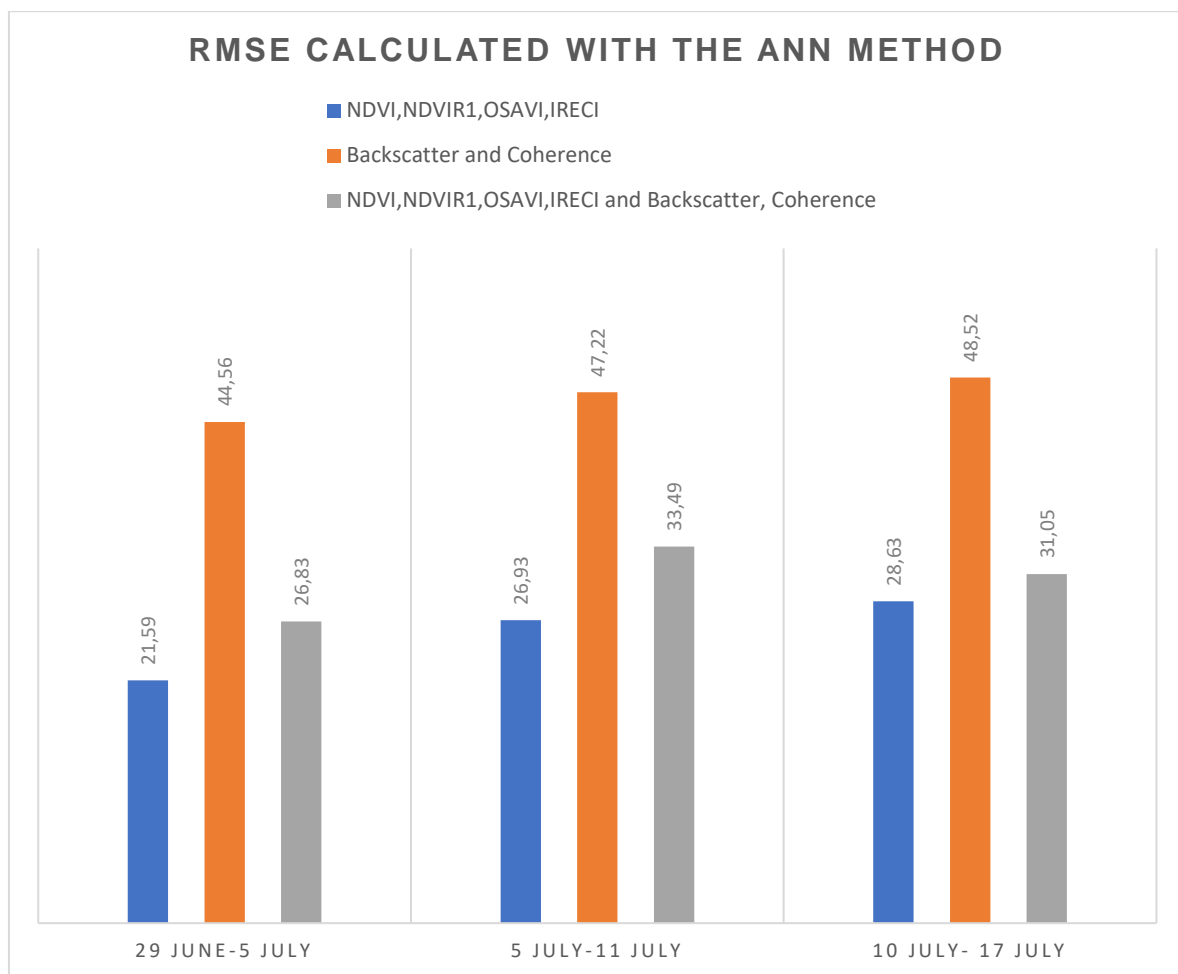

Figure 6.2. Average RMSE for optical, radar, optical, and radar.

7. CONCLUSIONS AND FUTURE WORK

In this thesis, a yield estimation study of 48 sunflower parcels taken from the Zile district of Tokat was conducted. The contribution of different combinations was investigated using optical and SAR satellite images, yield estimation was made with SLR and ANN methods, RMSE ve R^2 values were calculated and reference yield values and estimated yield values were compared. The results found are given below.

The following results were obtained when the yield was estimated using Sentinel-2 optical satellite images.

- When the yield estimation is made from NDVI, NDVIR1, OSAVI, and IRECI indices using the SLR method, the best result for June 30 was obtained from OSAVI ($R^2 = 0.77$ RMSE = 22.47 kg). NDVIR1 ($R^2 = 0.63$ RMSE= 30.44 kg) gave the best result for July 8. The index that gave the best result for July 10 was again NDVIR1 ($R^2 = 0.63$ RMSE= 29.33 kg).
- In the ANN method, when the indices are processed separately as input values, NDVI ($R^2=0.76$ RMSE= 22.07 kg) gave the best result on 30 June. NDVIR1 ($R^2= 0.64$ RMSE= 27.53 kg) gave the best result on July 8th. On July 10, NDVIR1 ($R^2= 0.71$ RMSE= 24.31 kg) gave the best result again.
- When the ANN method is compared with the SLR method, the ANN method gave better results than the SLR method in the three dates considered. As a result, it was concluded that the best estimation study was made in the ANN method in the NDVI and NDVIR1 indices.
- In the ANN method, when the four indices are processed together as input values, ANN gave better results than the SLR method on all three dates. The best result was obtained in the heading period on June 30 ($R^2=0.78$ RMSE= 21.59 kg). It has been concluded that using the indices together as input in the ANN method reduces the error rate in yield estimation.
- It was determined that it is possible to obtain the sunflowers' phenological stages and estimate yield in advance with higher accuracy by the ANN method using optical images.

The following results were obtained when the yield was estimated using Sentinel-1 SAR satellite images.

- When the yield was estimated using the backscatter values alone, the best result in the SLR method was obtained from the VH polarization on June 29 ($R^2= 0.14$ RMSE= 47.88 kg).
- When the yield was estimated using the backscatter values alone, the best result in the ANN method was obtained on 29 June VV polarization ($R^2=0,09$ RMSE= 42,46 kg).
- In the SLR method, backscatter values gave better results in VH polarization compared to VV polarization on all three dates. However, in ANN, VV polarization gave better results than VH polarization.
- The ANN method gave better results than the SLR method, but the backscatter values did not contribute enough. When the R^2 value and the average RMSE are compared with the values obtained in the index values, it is seen that the contribution of the backscatter values to the yield estimation is very small. It has been concluded that using the backscatter values alone in the yield estimation is not sufficient.
- When the yield was estimated using the coherence values, the best result in the SLR method was obtained in VH polarization between 29 June and 5 July ($R^2= 0.06$ RMSE= 47.17 kg).
- In the ANN method, the best result was obtained on July 5-11 in VV polarization ($R^2= 0.01$ RMSE= 46.24 kg).
- In the SLR method, VH polarization produced better values compared to VV polarization, but in the ANN method, VV polarization produced better values than VH polarization.
- In both polarizations (VH, VV), the ANN method gave better results than the SLR method but results with sufficient accuracy were not produced.
- It has been concluded that the use of coherence values alone in the yield estimation is not sufficient.
- When backscatter and coherence values are used together, although the error rate decreased on 29 June-5 July, it did not affect the error rate much on other dates. The combined use of backscatter and coherence values had little or no effect on the yield estimate.

- When backscatter and coherence values are used together, the error rate decreased (RMSE= 44,56 kg) on 29 June-5 July, while it increased the error rate on other dates. The combined use of backscatter and coherence values had little or no effect on the yield estimate.

The following results were obtained when the yield was estimated using backscatter and features of SAR (Sentinel-1) data and features of multi-spectral data (Sentinel-2).

- In the ANN method, when the indices, backscatter, and coherence values we obtained from the optical and SAR satellite images were processed as input values together, the ANN gave better results for all three dates than the SLR method. The best result was obtained in the heading period between 29 June - 5 July ($R^2=0.67$ RMSE= 26.83 kg).
- The estimated yield values were found with acceptable accuracy. However, the values did not improve.

The following are suggested for further studies:

- Yield estimation can be made with the ANN method by using more plant indices in future studies. Because when the 4 vegetation indices used in this study were used together as input in the ANN method, an improvement was observed in the yield estimation.
- In future studies, yield estimation can be made again by increasing the number of data because only 48 sunflower parcels were used in this study.
- The contribution could not be obtained from the backscatter and coherence values obtained from the SAR data using the ANN method and the SLR method for the yield estimation of the sunflower crop. This data should be re-examined by trying different machine learning and deep learning approaches such as Random Forest, SVM, and CNN.
- In this study, annual data for 2018 were used. It is recommended for future studies to re-examine and interpret yield estimation for longer periods using optical and SAR satellite imagery other.

CURRICULUM VITAE

Credentials

Name, Surname : İrem Ecem ASLAN
Place of Birth : İstanbul, Turkey
Date of Birth : 08.08.1995
Marial Status : Single
Address : Ankara, Turkey
Telephone : +90 507 084 44 54
E-Mail : ecemasln@icloud.com

Education

BSC. : Erciyes University, Department of Map
Engineering, Kayseri, Turkey (2019)

MSc. : -

PhD. : -
